MODERN APPARATUS

FOR
Resuscitation

ADEQUATE treatment of asphyxia and oxygen deficiency in all types of cases demands modern equipment for resuscitation and for the administration of oxygen to meet varying conditions. Ohio Kreiselman Resuscitators provide positive, reliable, safe control of gas pressure by automatic and regulator equipment which provides three stages of automatic pressure reduction. Kreiselman resuscitators are made in two general types: one designed essentially for use in asphyxia neonatorum, and the other for use in resuscitation of children and adults. All models embody identical principles and when equipped with proper sizes of masks are complete and adequate for the treatment of infants, children or adults. The catalog, "Kreiselman Resuscitators," mailed on request, gives complete details. For immediate detailed information, call our nearest branch sales office.

FROM POINT TO JUNCTION of cannula and hub, B-D NEEDLES hold a truer bore. Hubs are micrometer-gauged to assure uniform fit. Basic design of B-D needle points provides extra lateral cutting edges to achieve relatively painless penetration. Cannula and hub are joined by unique application of parallel longitudinal pressure to insure against leakage and against crimping of cannula. Buffing and finishing produce a velvet-smooth surface and inspection is rigidly maintained throughout every phase of manufacture.

HYPERCHROME STAINLESS STEEL tubing provides the optimal compromise in a needle stiff enough to hold a point without 'fish hooking', and flexible enough to withstand maximum bending without breaking.

NUMBER 1

THE RELIEF OF PAIN IN CHRONIC (CALCAREOUS) PANCREATITIS BY SYMPATHECTOMY

BRONSON S RAY, M D, and A DALE CONSOLE, M D, New York, New York

CHRONICALLY recurring pancreatitis may cause a wide variety of signs and symptoms but calcareous deposits in the parenchyma of the organ, demonstrable by roentgenograms, and pain are the features common to almost all cases as borne out by the recent reviews (2, 7, 8, 16). The pain which is chiefly in the midline of the upper abdomen may be referred to either or both upper abdominal quadrants and to the back. It is recurring or constant often becoming intolerable and in such cases constitutes the dominant problem in the treatment of the disease. Total or near total pancreatectomy has been recommended and employed by some (Whipple, Clagett (15), Zinninger, Parsons), but the operation is formidable, even unfeasible in some cases. Since relief of pain is the primary purpose of surgical treatment, the interruption of pain pathways from the pancreas may be considered as an alternate and relatively safe means of accomplishing the same end.

In 1945 Mallet-Guy, Jeanjean and Serretaz performed unilateral subdiaphragmatic splanchnicectomy in 11 patients for relief of pain from chronic pancreatitis. In these patients 10 operations were done on the left side, 1 on the right. Seven had complete relief of pain during follow-up periods varying from 6 to 35 months. Four had one or more attacks

of pain after operation. Smithwick reported complete relief of pain 6 months after resection of the right sympathetic chain from the third to the twelfth thoracic and right splanchnicectomy in 1 case. Fontaine, Forster, and Stefanini reported 1 case of "bilateral splanchnicectomy" for "chronic sclerosing pancreatitis" which seemed to have been effective in relieving pain. Reinhoff and Baker in 1 case performed bilateral resection of the sympathetic chains from the twelfth thoracic to the second lumbar, bilateral splanchnicectomy, and bilateral vagotomy with relief of pain and no recurrence after 10 months. Grimson, Hesser, and Kitchin treated 1 patient by removal of both celiac ganglia and of the superior mesenteric ganglion, but the pain returned after 5 months. deTakats and Walter performed a right splanchnicectomy and resection of the right sympathetic chain from the ninth to the twelfth thoracic in 1 patient with relief of pain and no recurrence after 6 months. Ray and Neill, in 1 patient, obtained partial relief of pain after resection of the right greater splanchnic nerve and the ganglionated chain from the seventh thoracic to the third lumbar but total relief after a similar procedure was performed on the left side.

The diversity of these procedures is confusing and leaves unsettled whether unilateral or bilateral deafferentation is required, whether the vagi may play any role in the transmission of pain impulses from the pancreas and how

From the Department of Surgery, New York Hospital, Cornell University Medical College.

extensively the sympathetic system need be resected for relief of pain. In this report, the case already referred to (11) will be described more fully and 4 additional cases of intractable pancreatic pain (3 cases of calcareous pancreatitis and 1 of pancreatic carcinoma) treated by sympathectomy will be added. Still another type of sympathectomy was employed in the latter cases than any heretofore described and since this might serve only to add to the confusion the available data regarding visceral pain pathways in man will be reviewed in an attempt to arrive at a rational approach to the problem.

CASE REPORTS

CASE 1 C T (No 465637), a 37 year old housewife and mother of 5 children, was admitted to the New York Hospital complaining of pain in the upper abdomen and back beginning 3 years before. At first the pain came in attacks lasting 2 to 4 days at intervals of 3 to 4 weeks, but gradually periods of freedom from pain diminished and for about 6 months pain had been constant. She had been confined to bed and had required daily doses of morphine for several months before admission to the hospital. The pain was described as severe, aching and boring in the epigastrium extending toward the right and left hypochondria and through to the back. Vomiting was frequent and there had been a weight loss of 20 pounds. There was no history of alcoholism and at another hospital an exploratory operation a year before had disclosed a normal gall bladder and common bile duct.

The abdomen was scaphoid, which facilitated the palpation of a moderately enlarged, hard, fairly movable and tender pancreas. Laboratory findings including the following were within normal limits: blood counts, urine, stool, serum protein, albumin-globulin ratio, blood amylase, glucose tolerance, gastric analysis, cholecystogram, and gastrointestinal roentgenograms. The abnormal laboratory findings included marked deficiency in amylase, lipase, and protease in the duodenal contents and evidence of extensive calcareous deposits throughout the entire pancreas on roentgenogram.

On January 15, 1947 a right sympathectomy was performed which included resection of the ganglionated chain from the seventh thoracic to the third lumbar and of the greater splanchnic nerve from the celiac ganglion to a point above the contribution of the seventh thoracic ramus.

Following operation she was relieved of her spontaneous pain although pressure over the head and body of the pancreas gave rise to moderate pain in the left upper abdomen. Thirteen days later, exploratory celiotomy under local anesthesia was performed; a biopsy of the pancreas taken and studies made on visceral pain sensation. Aside from the

pancreatitis no abnormalities were found. Stimulation of the head and body of the pancreas either by pressure or faradic current resulted in pain referred to the upper abdomen always to the left of the midline. This and other studies which have been reported (13) indicate that the pancreas has a bilateral sensory innervation.

The patient returned to her home, began to gain weight and take up her household duties. She was free of pain for 6 weeks after the first operation, then began to experience mild pain in the left upper abdominal quadrant. This gradually increased in intensity but never attained the degree of her original pain and was not attended by nausea and vomiting as before. The pain in the mid-epigastrium, right hypochondrium, and back did not recur.

On May 5, 1947, three and one half months after right sympathectomy, a left sympathectomy of similar extent was performed for relief of her residual pain. Following this operation her abdominal pain and tenderness were completely eliminated. She gradually resumed normal activity requiring several weeks to accommodate for a moderate grade of postural hypotension. She gained 20 pounds in weight and when last seen in June 1948 had remained asymptomatic.

CASE 2 C B (No 322099), a 47 year old woman (referred by Doctors William H. Lewis, Seward Erdman, and Allen O. Whipple), was admitted to the New York Hospital for the third time in 2 years complaining of abdominal pain. For 2½ years she had been subject to attacks of pain lasting from 1 to 10 days at intervals at first of several months but more recently of only a few weeks at the most. The pain was a severe deep aching sensation felt principally in the midepigastrium but also across the entire abdomen above the umbilicus and in the back at the upper lumbar level, it was accompanied by nausea and vomiting and required frequent doses of morphine for relief. There was a history of chronic alcoholism. In May 1945 and again in November 1946 the abdomen had been explored, each time disclosing normal abdominal viscera except for firm enlargement of the pancreas and several small 1 to 2 centimeter cysts in the head and body of the organ. A biopsy did not show malignancy of the pancreas.

Examination showed evidence of weight loss and a tender, firm palpable mass in the upper abdomen in keeping with a moderate enlargement of the head of the pancreas. The following laboratory findings did not show significant deviation from normal: blood counts, urinalysis, stool, serum protein, albumin-globulin ratio, blood urea nitrogen, blood amylase, glucose tolerance, cholecystogram, and gastrointestinal roentgenograms. However, roentgenograms of the abdomen showed extensive calcareous deposits through the entire pancreas (Fig 1).

On June 28, 1947, one stage bilateral sympathectomy was performed which included resection of the ganglionated chains from the eleventh thoracic to the first lumbar and of the distal 6 centimeters of the greater splanchnics (preserving the celiac ganglia).

Recovery from operation was prompt and her abdominal pain and tenderness were completely relieved. For the first 6 months she resumed normal activity, gained weight, and with the exception of 1 short episode of low grade fever and nausea 2 months after operation, which may have represented a painless recurrence of pancreatitis, she remained free of symptoms until December 1947. Then she developed persistent fever and a painless mass of gradually increasing size in the epigastrium. Abdominal incision disclosed the presence of an infected pancreatic multiloculated cyst and a fistulous tract has resulted. However, the patient has maintained a fair degree of nutrition and has remained free of pain for over a year.

CASE 3 A S (No 479792), a 43 year old woman, was admitted to the New York Hospital complaining of recurring bilious attacks for 2½ years. The attacks were characterized at first by nausea, vomiting, and pain across the upper abdomen, lasting from several hours to several days and occurring every 4 to 8 weeks. Six months before coming to the hospital she had a particularly severe attack with pain and tenderness across the upper abdomen and pain also across the back at the same level. She had low grade fever, a leucocytosis of 11,000 to 16,000 and signs of fluid in the abdomen. The attack gradually subsided but she was never wholly free of pain thereafter. She lost 12 pounds in weight, became semi-invalid and required opiates for the periods of more severe pain. At no time had she been jaundiced. She had been a moderate alcoholic for many years.

Examination showed evidence of moderate weight loss and tenderness without spasm on palpation across both sides of the upper abdomen. There was no fever. The following laboratory examinations did not show any abnormality: blood counts, urine, stool, serum protein, albumin-globulin ratio, blood amylase, glucose tolerance, cholecystograms, and gastrointestinal roentgenograms. But roentgenograms of the abdomen showed small calcific shadows scattered throughout the head and body of the pancreas.

On December 24, 1947 one stage bilateral sympathectomy was performed which included resection of the ganglionated chains from the eleventh thoracic to the first lumbar and of the distal 6 centimeters of the greater splanchnics (preserving the celiac ganglia). Recovery from operation was prompt and the relief of her former pain and tenderness was immediate.

On January 6, 1948 an exploratory celiotomy was performed. A light anesthesia of nitrous oxide was administered while the abdomen was opened and the pancreas exposed. The margins of the wound were infiltrated with procaine and the patient allowed to waken. Pressure, manipulation, and faradic stimulation of the head and body of the pancreas failed to elicit any pain. The pancreas was diffusely enlarged in moderate degree and unusually firm. The capsule of the gland was tough and incision into the gland for biopsy disclosed grayish, firm fibrotic tissue.

Fig 1 Roentgenogram in Case 2 showing extensive calcareous deposits in the pancreas outlining the entire organ. Similar deposits were demonstrated by roentgenogram in the other cases of pancreatitis.

Aside from these changes in the pancreas no other abnormalities of the abdominal viscera were observed on exploration. The biopsy of the pancreas showed "pancreatic tissues extensively fibrosed and the parenchyma distorted."

The patient left the hospital 3 weeks after the second operation. She has remained free of pain or digestive complaints, has gained weight and resumed her normal activities. She was last examined in July 1948.

CASE 4 L B (No 498521), a 45 year old male, was admitted to the New York Hospital complaining of recurring attacks of severe epigastric pain of 7 years' duration. The attacks were sudden in onset, frequently associated with nausea and vomiting, and occurred at least once each day. The pain frequently radiated to the back. He had consulted several physicians and had had 2 abdominal operations at one of which a biopsy of the pancreas was taken. The pathologist reported this as definite chronic pancreatitis. At the second operation a subtotal gastric resection was done presumably as a first stage procedure in removal of the pancreas. No ulcer was found.

The patient was a chronic alcoholic and a confirmed morphine addict. He had been eating poorly for several months, had lost a considerable amount of

formation makes it possible to set certain anatomic limits within which afferent nerves from the pancreas for example can be expected to pass.

Most nerves supplying the abdominal viscera traverse the celiac plexus which includes the celiac and mesenteric ganglia. Pathways for connections between the celiac plexus and the paravertebral ganglionated chains include the splanchnic nerves and a plexus about the thoracic aorta. Of the splanchnic nerves by far the most constant in structure and probably the most important from the standpoint of the transmission of afferent impulses is the greater splanchnic on each side. The lesser and least splanchnic nerves have an inconstant anatomic arrangement in man and are represented by a variable number of nerves which connect the celiac plexus to the upper lumbar and lower thoracic portions of the sympathetic chains, they may be conveniently referred to as the lesser splanchnic nerves. In addition to these pathways there may be direct connections between the viscera and the sympathetic chains which do not traverse the celiac plexus. Upon reaching the ganglionated chains, individual visceral pain fibers leave the chains at the same or at higher levels by way of the rami communicantes leading to the posterior (sensory) roots and to the cord.

A schematic diagram (Fig. 2) of the courses that pain fibers from the pancreas may take through the sympathetic system includes several possibilities.

Pathway *A* passes from the pancreas through the celiac plexus to the ipsilateral celiac ganglion. From that point it joins the greater splanchnic nerve or any lesser splanchnics through which it reaches the ipsilateral ganglionated chain and thence the cord.

Pathway *B* differs from *A* only in that it fails to pass through the celiac ganglion and passes directly from the celiac plexus to the thoracic ganglionated chain via the splanchnics. Such nerve fibers are seen occasionally during surgical operations in this region and while proof is lacking there is a good possibility that some are afferent fibers. Their presence might explain in part the failure of celiac and mesenteric ganglionectomy to relieve pancreatic pain as reported by Grimsor.

Fig. 2 Schematic diagram of pain pathways from the pancreas (P), celiac plexus, GS, greater splanchnic nerves, LS, lesser splanchnic nerves. Area within interrupted lines indicates the extent of proposed resection.

Pathway *C* passes through the celiac plexus but joins the contralateral ganglionated chain via the contralateral splanchnic nerves. That such pathways exist and provide a bilateral sensory innervation to the pancreas has been adequately demonstrated in previously reported studies (13).

Pathway *D* passes through nerves that may or may not traverse the celiac plexus but join the lumbar portion of the ganglionated chain and leave the chain at one of the lumbar levels without ascending to the thoracic levels. That such pathways exist has been proved at least for the ureter though not yet established for the pancreas.

Pathway *E* passes through the celiac plexus and ascends with the plexus about the thoracic aorta, leaving the aorta at various levels to join the thoracic ganglionated chain. If such a sensory pathway actually exists it is

likely that connections between the aortic plexus and the ganglionated chain occur through the greater splanchnic nerve though theoretically nerves apart from the splanchnic might connect with the chain in the upper thoracic levels as indicated in Figure 2, *L*. Since bilateral thoracolumbar sympathectomy from the seventh thoracic to the third lumbar and resection of the greater splanchnic nerves to a point above the contribution of the seventh thoracic rami apparently eliminate sensation in the upper abdominal viscera separate afferent pathways above the seventh thoracic level either do not exist or are not important in pancreatic pain.

The vagus nerves possess afferent fibers that have been thought by some to be visceral pain fibers though Cannon concluded from animal experimentation that these fibers are part of a visceral reflex arc and not pain fibers. The operation of bilateral sympathectomy and bilateral vagotomy employed for the relief of pancreatic pain by Richhoff and Baker suggests that they considered the possibility of the transmission of pain impulses via the vagi. The observations of Ray and Neill conclude that abdominal visceral pain sensation is mediated wholly by the sympathetic system. The aggregate observations of Grimson and associates also indicate that the vagus nerves do not play a role in the transmission of abdominal visceral pain.

Thus from these considerations it may be concluded that abdominal visceral analgesia and more particularly analgesia of the pancreas can be achieved by bilateral interruption of all splanchnic nerves. The term splanchnic nerves however is a loose one and includes the greater splanchnic nerves and all other nerve fibers connecting the celiac plexus with the lower thoracic and upper lumbar sympathetic chains. The most practical means of accomplishing interruption of the splanchnics is through the operation employed in all but Case 1, namely, bilateral resection of the greater splanchnics and of the sympathetic chains from the eleventh thoracic to the first lumbar.

The operative procedure is as follows. The patient is placed either in prone or lateral position; the latter is preferred. The twelfth rib

is resected, the pleura is reflected from the vertebral bodies and the crus of the diaphragm detached. The greater splanchnic nerve is divided at its juncture with the celiac ganglion and freed upward for 8 to 10 centimeters where it is again divided (or avulsed) and the segment removed. The ganglionated chain is then identified and the rami communicantes proximal to the eleventh and twelfth thoracic and the first lumbar ganglia are divided. The chain is divided above the eleventh thoracic and below the first lumbar ganglia and the segment removed. In the process of resecting the greater splanchnic and the ganglionated chain numerous lesser splanchnic nerves connecting them with the celiac plexus or with the pancreas directly will have been divided. The same procedure is carried out on each side and may be done at the same time or in two separate stages. Unless the patient's condition is especially precarious, both sides may safely be done at the same operation.

This operation may not represent the ultimate refinement in producing pancreatic analgesia but it is a relatively limited resection of the sympathetics and should be attended by a minimum of operative risk. With more experience it may be found necessary to remove more of the ganglionated chain for consistent results but it is more likely that less of it will require removal. If additional experience for example should show that there are no sensory fibers from the pancreas traversing the lumbar posterior (sensory) nerve roots then it would be unnecessary to resect the first lumbar sympathetic ganglion and the operation could be done entirely above the diaphragm. The operation then would be much like that employed by Peet for the treatment of vascular hypertension. Our experience however has shown that division of the attachment of the diaphragm adds no inconvenience and affords better exposure of the upper lumbar portion of the chain, the twelfth thoracic rami and of the lesser splanchnic nerves.

Although it is evident that bilateral sympathectomy is necessary in order to produce analgesia of the pancreas the reports of successful relief of pain by unilateral sympathectomy suggest that in some patients a unilateral operation may be adequate for the im-

vidual needs Our experience in Case 1, however, indicated that right-sided sympathectomy cannot be relied upon to relieve all the pain permanently, even though the early result appeared satisfactory, and that for total relief of pain and tenderness in the pancreas a bilateral operation was ultimately necessary. Similarly, a patient (No 73332, Hospital of the University of Pennsylvania) with chronic calcareous pancreatitis upon whom Dr J E Rhoads performed a right splanchnicectomy and resection of the ganglionated chain from the tenth thoracic to the second lumbar had relief of pain for 1 month only After left sympathectomy relief of pain was complete Eckel and Dickinson at the Bronx Veterans Hospital performed a right splanchnicectomy and resection of the ganglionated chain from the seventh thoracic to the second lumbar on a patient with chronic calcareous pancreatitis Pain relief was partial and transient and left sympathectomy will be done at a later date

It is difficult to reconcile these reports and our experience with the reports of Mallet-Guy and associates, Smithwick, and deTakats Each of these has reported lasting and complete relief of pain with unilateral sympathectomy (4 of the 11 patients reported by Mallet-Guy and associates, however, had recurrence of pain) The fact that either right or left deafferentation appears to be equally efficacious in these reports tends to confirm the impression that the pancreas has bilateral sensory innervation and suggests that either unilateral operation is an incomplete deafferentation It must be concluded, then, that absolute analgesia of the pancreas can be achieved only by bilateral sympathectomy Partial deafferentation in some patients, however, may be sufficient to give relief of pain

The question of possible unwelcome effects from bilateral sympathetic resection may aptly be raised for it must be appreciated that any operation in which nerves are cut in order to relieve pain imposes a certain degree of compromise by which one undesirable situation is to be replaced by another which is less undesirable but still acceptable A sympathectomy of the extent proposed may produce some alteration in blood pressure even in normo-

tensive people but after the initial postoperative period in which symptoms may occur from postural hypotension there should be no notable untoward effects from this source Also, a sympathectomy to deafferent the pancreas cannot be made selective enough to avoid producing the same effects in other abdominal viscera, chiefly the gastrointestinal tract Thus, as a result of the operation the visceral pain component of certain abdominal diseases, such as peptic ulcer, cholecystitis, and appendicitis is eliminated But other symptoms and signs of acute abdominal diseases such as fever, leucocytosis, nausea, vomiting, distention, jaundice, and pain and tenderness from parietal peritoneal irritation (via somatic afferent nerve pathways) would still be present to provide as much warning to the alert physician as exists in some unsympathectomized people with the same diseases The operation which has been proposed does not affect other gastrointestinal functions or the sexual and reproductive functions of either male or female

SUMMARY AND CONCLUSIONS

Chronic (calcareous) pancreatitis is often accompanied by pain so intolerable that some surgical measure is necessary for relief Total or near total pancreatectomy is one method of treatment but it is not always feasible and at best is accompanied by a considerable operative risk and further deprivation of endocrine and enzyme products The alternative procedure of interruption of the pain pathways from the pancreas is a safer method and the side effects of the operation are not serious

A review of the several reports of differing procedures for interruption of the pain pathways from the pancreas, together with our own experience in 5 cases of intractable pancreatic pain (4 cases of chronic calcareous pancreatitis and 1 pancreatic carcinoma) has led to the following conclusions

- 1 Pain sense from the pancreas is mediated by visceral afferent nerves that traverse the celiac plexus, the splanchnics, and the sympathetic chains on both sides

- 2 The vagus nerves play no part in the transmission of pain sense from the pancreas

3 The principal pathway traversed by pain fibers from the pancreas is via the greater splanchnic nerves, but lesser splanchnic nerves the lower portion of the thoracic chains and possibly the upper portion of the lumbar chains may also serve as pathways

4 The minimal operation thus far found to provide total analgesia of the pancreas and the one proposed as most suitable is bilateral resection of the ganglionated chains from the eleventh thoracic to the first lumbar and of lowest 8 centimeters of the greater splanchnic nerves

5 Unilateral, right or left, sympathectomy may in some patients provide interruption of enough of the sensory supply to afford relief of pain

6 While the operation is well suited to the relief of intractable pain of chronic pancreatitis it is of limited value in carcinoma of the pancreas chiefly because of the tendency of the disease to spread outside the organ to pain sensitive areas supplied by somatic sensory nerves

BLOOD AND "AVAILABLE FLUID" (THIOCYANATE) VOLUME STUDIES IN SURGICAL PATIENTS

Part I Normal Patterns of Response of the Blood Volume, Available Fluid, Protein, Chloride, and Hematocrit in the Postoperative Surgical Patient

RICHARDS P LYON, M D, JOSEPH R STANTON, M D, EDWARD D FREIS, M D, and
REGINALD H SMITHWICK, M D, F A C S, Boston, Massachusetts

THE blood, protein, and crystalloid requirements of the surgical patient are usually estimated on the basis of the history and the values for the hematocrit, protein, and chloride. In states of dehydration, normal values for the laboratory determinations may mask a severe, underlying depletion of the total amount of red cells, protein, or chloride in the body. Conversely, in overhydration and hemodilution with or without the presence of clinically detectable edema, abnormally low values may be found for the concentration of these substances in the blood even though the total amount in the body may be at or close to normal levels. The obvious importance of changes in the size of the blood volume and available fluid in the interpretation of such concentration measurements is not generally appreciated.

The studies in this series represent further efforts to establish the patterns of response of the blood and available fluid volumes in the postoperative patient and in addition to suggest correlations that may exist between such total volume changes and the usual concentration measurements. Through such a program not only will the limitations of the routinely employed laboratory tests be more clearly defined, but in addition their proper interpretation in the assessment of the requirements

From the Surgical and Medical Services, Evans Memorial, Massachusetts Memorial Hospitals, and the Departments of Surgery and Medicine, Boston University School of Medicine, Boston, Mass.

Presented in part before the Clinical Congress, American College of Surgeons, New York, September 1947.

of the postoperative patient for blood, protein, and crystalloids may be established.

MATERIAL AND METHODS

Twenty patients, from the ward and private surgical services of the Massachusetts Memorial Hospitals, were subjected to a variety of major general surgical procedures. All patients were considered to be in normal nutritional and fluid balance prior to operation and, except where specifically noted (Table I), received 2000 to 3000 cubic centimeters of 5 per cent glucose in water on the operative day, followed by oral fluids and house diet as tolerated on succeeding days. Blood loss occurring during operation was measured as described in a separate communication (22). Replacement of operative blood loss was withheld in 10 patients. Three to 10 sets of detailed observations were carried out in the preoperative and 10 day postoperative period (Table I).

Plasma volume was determined by a 0.1 per cent solution of Evans blue dye (T1824) according to the method of Gibson and Evans, adapted (10) and modified (11) for use with the Coleman junior spectrophotometer. Dyed samples were corrected for fluid shifts as suggested by Gregerson. Plasma protein concentration was determined by the falling drop method of Barbour and Hamilton. The total blood volume and red cell volume were computed from the hematocrit and plasma volume (13) and the total circulating protein from the plasma volume and plasma protein concentration. Plasma and urine chlorides were determined by the Van Slyke and Hiller modifi-

cation of the Sendroy method (18). As described elsewhere (11), a 5 per cent solution of sodium thiocyanate was injected intravenously to measure the "available fluid" volume. The thiocyanate ion permeates the plasma and extracellular water, and, in addition, a small amount enters the red cells. In effect it measures the volume of the total extracellular fluid compartment including the plasma volume. In this paper the terms "available fluid," "extracellular fluid," and "thiocyanate space" are used synonymously and refer to the total extracellular compartment of the body water as determined by the thiocyanate method.

RESULTS

Available fluid and chloride concentration. Changes in "available fluid" volume following operation paralleled and were related to the degree of hydration. In 16 cases increases in the available fluid volume of from 16 to 26 per cent were noted by the third postoperative day, representing additions of from 2 to 5 liters of fluid to this compartment (Fig. 1). In

7 cases the "available fluid" was determined within 24 hours following operation and in 6 of these increases in the "available fluid" volumes were observed to have already occurred. Although tending to return slowly toward preoperative values after the fourth day, the "available fluid" compartments generally remained enlarged above preoperative levels for at least 2 weeks following surgery. The greatest increase (26 per cent) in "available fluid" observed in the series occurred in the 1 patient who received normal saline parenterally (Table I, Case 12).

Postoperative decreases in the "thiocyanate space" were noted in 4 of the 20 cases (Fig. 2). Three of these patients were in negative water balance in the early postoperative period (Table I, Cases 5, 6, and 7). In 2, extrarenal water and salt losses through vomiting and gastric suction were unreplaced, and in the third, a 64-year-old man subjected to a transurethral prostatic resection, there was an excessive urine volume which equalled the fluid intake. The fourth patient underwent a high

Fig 1 Illustrates the percentage increases above pre-operative (normal) values in extracellular fluid in the post-operative period in 16 of the 20 cases of this series. All 16 cases were in positive fluid balance.

Fig 2 The percentage decrease in extracellular fluid in 4 cases known to be in negative fluid balance postoperatively. Note consistent decrease as opposed to increase when patient is adequately hydrated, e.g., Figure 1.

thigh amputation which of necessity resulted in the loss of a significant portion of the extracellular space.

Plasma and urine chlorides were determined daily in 5 cases which showed simultaneous postoperative increases in the available fluid volume. All exhibited decreases in the plasma chloride concentrations of from 7 to 12 milliequivalents per liter coincident with the increase in the "available fluid" volume (Fig 3). Plasma chloride concentration tended to return to preoperative levels about the fifth day. Oral salt intake was not limited save during the period of obligatory intravenous therapy, yet daily total salt outputs in the urine were low, ranging from 1.5 to 3.7 grams on the operative and first 3 postoperative days. Retention of salt also occurred in the 1 patient (Table I, Case 12) who received parenteral saline on the first postoperative day, the intake being 13.5 grams and output 3.36 grams of salt.

In addition to retention of salt, retention of water occurred as indicated by a low urine volume in relation to the fluid intake. The 24-hour urine volumes ranged from 600 to 1000 cubic centimeters during the first 48 hours following operation despite the administration by mouth or parenterally of 3 to 5 liters of fluid during this period.

Therefore, in all cases presumed to be in positive water balance following operation, evidence of fluid retention was manifested by increased "available fluid" volumes, depression of the plasma chloride concentrations,

Fig 3 Illustrates percentage change in available fluid, below, and the decrease in plasma chloride concentration, above, noted in 5 cases following operation and demonstrates decrease in chloride concentration accompanying "available fluid" space increases. Chlorides expressed as milliequivalents per liter and available fluid as per cent change from preoperative (control) value.

Fig 4 Illustrates parallel changes in extracellular fluid and plasma volume. Note that plasma volume is below the preoperative level in both instances in which the extracellular fluid was below preoperative values

and decreased urinary output of water and salt. In cases known to be in negative water balance postoperatively, corroborative evidence of inadequate hydration was afforded by the decreases observed in the "available fluid" volume during this period.

Plasma volume. Plasma volume changes in general tended to reflect the changes in "available fluid" (Fig 4). In addition the degree of change was closely related to the extent of blood loss. It is noteworthy that following operative blood loss, plasma volume replacement did not take place in any case in the series unless the "available fluid" volume was equal to, or above, the preoperative level.

In the 10 patients who received no operative blood replacement, the pattern of change of plasma volume over the 10 day observation period followed remarkably similar trends. The general pattern of change is demonstrated by the following 2 cases (Figs 5 and 6). In the first case (Fig 5), a cholecystectomy had been performed with a blood loss of 150 cubic centimeters. Restoration of plasma volume did not begin until after the fourth postoperative hour, but at the 24th hour, operative plasma losses amounting to 90 cubic centimeters had been replaced. The plasma volume in this case continued until the third day, overshooting by 17 per cent at this time and declining toward the preoperative value over the suc-

ceeding 7 days. Similar plasma volume changes following a larger uncompensated blood loss of 1080 cubic centimeters are charted in Figure 6. After the fourth hour, and before the 24th hour, the plasma volume increased by 690 cubic centimeters, returning to preoperative levels. Plasma volume continued to increase, the maximum point of overshoot occurring on the third day and finally returned to the preoperative value on the fifth day.

The plasma volume changes in the 10 untransfused, but adequately hydrated, patients are plotted in Figure 7. Four trends can be observed in the 9 cases which exhibited increased "available fluid" volumes: (a) little to no plasma volume replacement occurred within the first 4 postoperative hours, (b) replacement of plasma losses of all magnitudes observed in this study tended to occur by the 24th hour, (c) the maximum point of plasma volume "overshoot" was reached on the third day, and (d) plasma volume decreased after the third day, tending to return to preoperative levels by the 10th and 14th day. By contrast, in the single patient of this group in whom the "available fluid" volume was decreased after operation, the plasma volume remained 6 to 10 per cent below the preoperative level for 7 days, showing no attempt toward restoration to the preoperative level thus illustrating the dependence of the plasma volume on the state of hydration as manifested in the available fluid volume.

Red cell volume. In the adequately hydrated patient, while the replacement of plasma and available fluid volumes following the blood loss associated with surgery was rapid, the red cell volume usually failed to change significantly from the level observed immediately after operation throughout the period during which the extracellular fluid and plasma volumes were increased. However, in several cases in which postoperative blood loss occurred, the red cell volumes exhibited further postoperative decreases reflecting the extent of blood loss after operation. The significance of uncompensated operative and postoperative depletion of red cell volume following certain types of operative procedures is discussed in another communication (22).

Fig 5 Illustrates in detail postoperative plasma volume increase after cholecystectomy in patient with blood loss of 150 cubic centimeters. Note concomitant hematocrit decrease and total blood volume increase.

Fig 6 Plasma volume increase after uncompensated blood loss of 1100 cubic centimeters after 1st stage lumbo-dorsal splanchnicectomy. Plasma volume overshoot failed to restore total blood volume to preoperative levels.

Total blood volume Since the red cell volume showed little fluctuation following the period of actual blood loss the total blood volume change closely reflected the fluctuations previously noted in plasma volume. As with plasma volume, blood volume losses tended to remain unreplaced during the first 3 or 4 hours postoperatively. The point of maximum blood volume increase usually occurred on the third post-blood-loss day (Figs 5, 6), corresponding to the point of maximal plasma volume increase, then gradually receded during the succeeding 7 days as the plasma volume returned toward preoperative levels.

Blood volume responses could be divided into two groups in relation to the amount of blood loss (Fig 7). Group A with blood losses of less than 400 cubic centimeters exhibited plasma volume "overshoots" adequate to replenish completely both plasma and red cell losses, and to restore blood volume to preoperative levels by the third postoperative day. Group B in which blood loss was in excess of 400 cubic centimeters produced plasma volume increases which were in general greater than those of group A and completely restored the plasma volume losses. However, plasma volume overshoots in group B were insufficient to compensate completely for the excessive red

cell loss. In group B, therefore, the total blood volume was not restored to the preoperative values.

Hematocrit Within the first 3 to 4 hours following operation the hematocrit varied negligibly from preoperative values. Subsequently, it fell steadily for 3 days reflecting the plasma volume increase. Minimum hematocrit values were recorded between 70 and 80 hours following blood loss corresponding with the time of maximum plasma volume increase. With blood losses of less than 200 cubic centimeters the maximum hematocrit fall at 24 hours was 2.4 millimeters per cent and at 72 hours 4.4 millimeters per cent. Where blood loss was from 200 to 500 cubic centimeters, the maximum 24 hour reduction was 3 millimeters per cent and the 72 hour fall 4 millimeters per cent. With uncompensated blood losses of between 500 and 1500 cubic centimeters the hematocrit decrease at the end of 24 hours ranged from 4 to 6 millimeters per cent and at the end of 3 days from 5.5 to 11 millimeters per cent. In general, therefore, in the group in which the blood loss was great the extent of the hematocrit fall at the end of 72 hours was directly related to the amount of blood loss, provided the patient was in positive fluid balance.

Fig 7 Illustrates percentage changes in plasma and total blood volume. The two distinct patterns of blood volume response are related to the amount of blood loss. Total blood volume was completely restored by plasma volume overshoots in cases in which blood loss was less than 400 cubic centimeters. With blood loss in excess of 400 cubic centimeters plasma volume overshoots were insufficient to restore total blood volume to preoperative values. Dotted line represents the only patient in this group who was in negative fluid balance and blood volume, plasma volume, and "available fluid" were below preoperative values.

From the third to the tenth days, the hematocrit value tended to rise as plasma volume overshoots were dissipated. However, in no case did the hematocrit return to preoperative levels by the tenth day unless the red cell volume had been restored completely by transfusion.

Circulating protein. Changes in total circulating protein closely paralleled those of plasma volume (Fig 8). The decreases in total circulating protein within the first four postoperative hours were consistent with the amount of blood loss. Following this period, and within 24 hours, additions of from 5 to 25 grams of protein occurred, usually restoring the total circulating protein to within 3 per cent of the preoperative values. The addition of protein to the plasma most often continued until the third day with overshoots of 5 to 15 per cent, representing daily gains of 12 to 25 grams of protein to the circulation. After the third day the total circulating protein diminished toward normal preoperative levels, continuing to parallel plasma volume changes.

As with the hematocrit, plasma protein concentration varied negligibly from preoperative levels during the first 3 to 4 postoperative hours. However, in contrast to the sub-

sequent increases in total circulating protein, the plasma protein concentration fell 2 to 15 per cent by the 24th hour, reflecting in some degree the simultaneously occurring plasma dilution. This decreased plasma protein concentration was maintained in 15 of the 20 cases during the first 5 postoperative days, and in more than 10 cases throughout the 10 day period of observation. At no time was it possible to judge the amount of the total circulating protein, or recognize increases in total circulating protein above preoperative levels by observation of the plasma protein concentration alone.

DISCUSSION

Data gathered in this study indicate that postoperative changes in the blood, and extracellular fluid volumes as well as in the hematocrit and protein follow a number of well defined patterns. (1) Retention of water and salt in the extracellular compartment tends to occur in the patient in positive fluid balance and is manifested by a decreased urine volume and an increased "available fluid" volume, with dilution of the extracellular salt, and consequent decrease in the plasma chloride concentration. (2) Changes in plasma volume tend to parallel and depend upon changes in the "available fluid." (3) Total circulating protein usually varies with plasma volume. (4) Plasma protein concentration usually decreases and tends to remain low due to plasma dilution even though total circulating protein values rise well above preoperative levels. (5) When uncompensated blood loss has occurred, the hematocrit tends to fall significantly for 3 days and reflects the increase in plasma volume. (6) If adequate hydration is maintained, the hematocrit value in the presence of uncompensated blood loss ordinarily does not return to preoperative levels within the 10 day convalescent period.

Retention of water and salt. The tendency of surgical patients to excrete a small volume of urine despite a large fluid intake in the early postoperative period is a common clinical observation. Detailed fluid balance studies have demonstrated that even the well hydrated surgical patient tends to retain both salt and water after operation (1, 6, 23). Enlargement

of the "available fluid" compartment as measured by thiocyanate has been observed following various types of disease and operation (11, 15, 16, 20). Eighty per cent of the cases in the present study exhibited similar increases in the "available fluid" volume which took place within 24 to 72 hours following surgery. That such increases in "available fluid" volume were most probably dependent on the state of hydration is demonstrated by the 3 cases in the series who were in negative fluid balance following operation and in whom the "available fluid" fell below the preoperative values. Depression of urinary water and salt output was consistently observed in the 5 patients subjected to special chloride studies, confirming the reports of Collier and of Abbott.

Plasma volume Plasma volume recovery following surgical blood loss occurred in this series only in the 16 patients who were in positive fluid balance and exhibited normal or enlarged "available fluid" compartments. The dependence of plasma volume upon the "available fluid" volume and state of hydration has been noted previously under experimental conditions in dogs by Mellors, Muntwyler, Mautz, and Abbott (17). Furthermore, following acute hemorrhage in dogs, plasma volume replacement is greatest and most rapid in animals given infusions of crystalloids (19). Warren and his co-workers maintained plasma volume and prevented shock in dogs following extensive plasmapheresis by the administration of crystalloid solutions to the point of edema formation, and on this basis have suggested that interstitial fluid pressure, a function of the extracellular fluid volume, is the agent of importance in maintaining or increasing plasma volume under these conditions.

In the present studies the pattern of time relationships of plasma and "available fluid" volume responses suggests that in the adequately hydrated postoperative patient a similar mechanism for the preservation of blood volume may be activated in man. Following a latent period of 3 to 4 hours after operation there began a simultaneous increase in "available fluid" volume and plasma volume (as well as total circulating protein) which uniformly reached a maximum on the third day.

Fig 8 Illustrates percentage changes in plasma volume, total circulating protein, and plasma protein concentration. Note predominant decrease in plasma protein concentration in spite of increase in total circulating protein accompanying plasma volume increases.

A similar 3 day pattern has been noted following large venesections in both animals (9, 19, 24) and man (8). Rapid recovery of plasma volume and associated circulating protein has been noted following war wounds where blood losses of as much as 2000 cubic centimeters occurred on the battlefield (4). Likewise, Co Tui and associates consistently observed that in man plasma volume appeared to be completely restored between large venesections repeated at weekly intervals.

The remarkable ability of plasma volume to restore itself within 24 hours and then to overshoot after surgical blood loss of from 100 to 1500 cubic centimeters was a consistent observation in this study. It is interesting to note that in the patient who suffered further blood loss on the second postoperative day, the point of maximal increase was delayed for an additional 3 days, suggesting that the 3 day pattern of response may be expected to occur after postoperative as well as operative blood loss.

Plasma protein In patients who were well nourished and hydrated prior to surgery, plasma protein synthesis and transfer from body stores were more than adequate to replenish all operative plasma protein losses ob-

served in this series. As much as 70 grams of protein were added to the plasma in the first 72 hours after operation. The minimum response observed was usually sufficient to restore the total circulating protein to preoperative levels by the 48th hour.

Despite the postoperative increases in total circulating protein noted in the present study, the plasma protein concentration decreased by from 0.2 to 1.0 gram per cent in three-fourths of the cases studied. Such decreases usually appeared within the first 24 hours following operation, simultaneously with the addition of large amounts of protein and fluid to the circulation, and reflected plasma dilution.

Decreases of as much as 0.5 gram per cent in the plasma protein concentration have been noted following many general surgical procedures (5). These findings confirm parallel observations in dogs subjected to hemorrhage (19, 24) and suggest that plasma protein concentration is an unreliable index of the amount of total circulating protein during the period of recovery from acute blood loss. Abbott (2) has previously suggested the unreliability of the plasma protein concentration as a guide to the nutritional status of the postoperative patient and suggested that the measurement of the total amount of circulating protein may be more reliable. In the present study decreases in plasma protein concentration were a normal occurrence in the adequately hydrated patient following surgery and the plasma protein concentration gave no indication of the relatively large increase in total circulating protein which frequently occurred in the postoperative period.

Hematocrit and red cell volume. In contrast to the rapid synthesis of plasma protein and the remarkable restoration of plasma volume in the adequately hydrated postoperative patient, the replacement by the body of major acute depletions of the red cell volume was severely limited. Though reticulocytosis was repeatedly demonstrated in cases in which blood losses were 500 cubic centimeters or more, none the less restoration of the red cell volume by hematopoiesis was slow and often imperceptible during the 10 day period following such loss. Additional experience (21)

has demonstrated that in certain cases where extensive depletion of the red cell volume occurred through either operative or postoperative blood loss, restoration of red cell volume may be incomplete, even 6 to 8 weeks after operation. The recognition of this fact has suggested that since plasma volume and circulating protein most often recover rapidly following operation, attention to, and restoration of, a depleted red cell volume by means of infusions of red cells suspended in saline may be worthy of consideration in specific instances.

A consistent finding in this study, 3 days after an uncompensated operative or postoperative blood loss, has been the fall in hematocrit which usually reflects both a deficit in red cells and an increase in plasma volume. A hematocrit that continues to fall after the third day suggests postoperative blood loss. In the present study, hematocrit decreases of 4 millimeters per cent or more within the first 24 hours, and 6 millimeters per cent or more by the third day could not be accounted for on the basis of increase in the plasma volume alone and indicated uncompensated blood loss in excess of 500 cubic centimeters (22). Furthermore, because of the tendency of plasma volume to decrease after the third postoperative day and to stabilize at its approximate preoperative level by the tenth day, a decreased hematocrit 10 days after surgery, at the time when most patients leave the hospital, is indicative of a depleted red cell volume. In our experience the most reliable simple laboratory test for the recognition of uncompensated red cell loss was a decrease of 5 millimeters per cent or more in the basal hematocrit drawn on the third postoperative day.

SUMMARY

Twenty patients, the subjects of major surgical procedures, were studied preoperatively and throughout an 8 to 10 day period following operation. Definite patterns of response were noted postoperatively in the blood, "available fluid," plasma, and red cell volumes as well as in the plasma protein concentration, hematocrit, and total circulating protein. The influence of the state of hydration and amount of blood loss on the patterns

of response of these volumetric compartments and concentration measurements is described, and the significant interrelationships are discussed

CONCLUSIONS

1 Following blood loss, the mechanism for the preservation or restoration of the total blood volume appears dependent upon a state of positive fluid balance

2 With patients in negative fluid balance following operation, recovery of the "available fluid," plasma, and total blood volumes is delayed until a state of positive fluid balance is established

3 In the absence of excessive extrarenal water and salt loss, a daily ration of 2 to 3 liters of 5 per cent glucose in water under the conditions of this study was adequate to establish positive fluid balance and to insure plasma volume recovery

4 When depleted through either operative or postoperative blood loss, the red cell volume shows little tendency to recover spontaneously within the first 10 days following operation

5 In the adequately hydrated patient, serial determinations of the basal hematocrit offer the most useful index of uncompensated blood loss

6 Postoperative decreases in the plasma protein concentration of from 0.2 to 1.0 gram per hundred cubic centimeters are not necessarily indicative of either inadequate nutrition or a depleted total amount of circulating protein

CLINICAL STUDIES OF THE HEPARIN COFACTOR

WILLIAM D HOLDEN, M D , F A C S , JACK W COLE, M D , and
JOHN H DAVIS, JR , M D , Cleveland, Ohio

THE fact that some surgical patients develop postoperative venous thrombosis whereas others do not remains a challenging problem in spite of the formidable array of facts available concerning the coagulation of blood and the peripheral circulation. There is little doubt that disturbances of the peripheral venous circulation and the coagulation of the blood are the principal factors involved in the pathogenesis of venous thrombi. The coagulability of the blood may be increased theoretically by any means whereby the total production or the rate of production of thrombin is increased. One manner in which the amount of effective thrombin may be increased is by a reduction in the quantity of thrombin-inactivating agents in the blood. This study was undertaken to determine whether operative procedures altered the thrombin-inactivating substances of the blood and whether any such alteration could be related to the development of venous thrombosis.

Thirty years ago, Howell (7) demonstrated that heparin itself is not an antithrombin agent in that it did not prevent the conversion of fibrinogen to fibrin in the presence of thrombin. The addition of a cofactor found in plasma or serum, however, rendered the heparin strongly antithrombogenic. These observations were confirmed by Quick (11).

The heparin cofactor is designated throughout this paper as the substance in the circulating blood which develops strong antithrombin capacity when heparin is added to it. The heparin cofactor has been designated by a variety of terms such as thrombin co-inhibitor (2), albumin X (12), proantithrombin (18), and heparin complement (19). Its composition is unknown. It is known, however, to be intimately associated with the blood proteins

(7, 11). More specifically, it is most closely associated with the serum albumin. Ziff and Chargaff (19) observed in a study of the heparin cofactor by means of electrophoresis that the fast and middle fractions of the albumin were most active as cofactors. Chargaff, Ziff, and Moore (3) also demonstrated some cofactor activity in some globulin fractions. Crystalline albumin has been found to be completely inactive as a cofactor (5). Howell (6) and Quick (11) found cofactor activity to be present in serum as well as plasma in various experimental animals. Astrup and Darling (2), on the contrary, found no thrombin co-inhibitor (heparin cofactor) activity in serum prepared from ox blood by either recalcification of plasma, removal of fibrinogen by the addition of a small amount of thrombin, or by denaturation of fibrinogen by heating to 56 degrees C for 3 minutes. Quick (11) found that both antithrombin and the heparin cofactor were destroyed at 67 degrees C and postulated that the two were identical. The addition of heparin according to Quick intensified the activity of the natural antithrombin of the blood.

Seegers and associates (14) demonstrated clearly that heparin acts as a catalyst in inactivating thrombin, and that it does not increase the capacity of plasma for neutralizing thrombin. It merely accelerates the process. If given sufficient time, the cofactor inactivates the same amount of thrombin without the assistance of added heparin.

Reasonably accurate measurements of the antithrombin activity of plasma or serum have been possible only since the purification and standardization of thrombin. Measurements of antithrombin activity are made by determining the amount of thrombin inactivated in a thrombin-plasma or thrombin-serum mixture under standard conditions. Heparin cofactor measurements are determined in a similar fashion except that heparin is added to the plasma or serum prior to the addition of

From the Laboratory of Surgical Research, Western Reserve University and University Hospitals of Cleveland.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Los Angeles, October 18 to 22, 1948.

TABLE I—RELATIONSHIP BETWEEN TIME OF INCUBATION OF SERUM AND DESTRUCTION OF HEPARIN COFACTOR

Time of incubation	Heparin cofactor units
None	97.2
10 min at 56° C	96.2
30 min at 56° C	0

thrombin. Methods for assaying the anti-thrombin activity of the blood have been devised by Wilson (18), Astrup and Darling (1), Seegers and Smith (13), and Hurn and Mann (9).

The heparin tolerance test (coagulability of the blood after the intravenous injection of 10 mgm of heparin) described by deTakats (4) and the *in vitro* test of the coagulability of the blood (17) after varying quantities of heparin are added probably represent in part the quantity of heparin cofactor available in the blood. Other factors such as the amount of thromboplastin and thrombin and the rate of conversion of prothrombin to thrombin may contribute to variations in the results of the tests.

Volkert and Piper (16) found an increase of antithrombin in the blood of patients with multiple pulmonary embolism, but normal values were found in patients with minor or moderate thrombotic disorders. They also observed no change in 21 patients who underwent various surgical procedures and developed no thromboembolic complications. Nielsen found antithrombin activity within normal limits in 6 patients with thrombotic diseases. Hurn, Barker, and Mann (8) performed antithrombin determinations on 57 patients who had evidence of either venous or arterial thrombosis and found an average value approximating that of normal individuals. Of the 57 patients, 18 had values above 120 per cent or below 80 per cent of normal. No mention is made of the interval lapsing between the onset of the thrombosis and the time of the antithrombin assays. Volkert (15) found in a study of rabbits that a coagulative irritant such as a silk suture in the wall of a vein elevated the blood antithrombin whether thrombosis occurred or not.

MATERIALS AND METHOD

Heparin. Various commercial heparin preparations were used, all of which contained 10

Fig 1 Relationship between the clotting time in seconds and the concentration of thrombin in units. The clotting time is also expressed as reciprocal minutes $\frac{60}{r}$.

milligrams per milliliter. The heparin was kept in a refrigerator and a 1/100 dilution was made each day. One-tenth milliliter containing 0.01 milligram was used for each determination of the heparin cofactor.

Thrombin. Hemostatic globulin was used undiluted. The thrombin was assayed by comparing its activity to a standard thrombin preparation of known strength.

Fibrinogen. Fraction I was prepared each day so that a 1.65 per cent solution in normal saline was obtained. The fibrinogen was used within 2 hours after being put into solution.

Saline. Normal saline was used to adjust the mixtures to a constant volume.

Serum. Serum was obtained from whole blood drawn during a fasting state. It was inactivated at 56 degrees C for 10 minutes, 0.1 milliliter of undiluted serum was used for each determination. Contrary to Astrup and Darling's (2) observation that heating of the serum to 56 degrees C for 3 minutes destroyed the cofactor, we found but slight inactivation when the serum was heated for 10 minutes at 56 degrees C. When heated at this temperature for 30 minutes, however, complete inactivation resulted (Table I). In spite of the fact that a small amount of cofactor activity

Fig 2 Relationship between the percentage destruction of thrombin and the amount of thrombin added to the serum

was destroyed by incubating the serum for 10 minutes at 56 degrees C, it was considered advisable to continue using this incubation period because of the complete inactivation of any remaining thrombin or prothrombin in the serum

By using serial dilutions of thrombin, the curve shown in Figure 1 was plotted. The abscissa represents dilutions of thrombin and the ordinate the clotting time in seconds. The thrombin was mixed with 0.8 milliliter of saline and 0.1 milliliter of inactivated serum. One-tenth milliliter of the 1.65 per cent fibrinogen solution was quickly added and a stop watch started. End points were distinct and determined by the first actual flocculation of fibrin. All determinations were done between 24 and 28 degrees C. Variations in the clotting times were found beyond this temperature range. By converting the clotting times in seconds to reciprocal minutes $\frac{60}{t}$, a linear relationship may be established between clotting times and concentrations of thrombin throughout the ascending part of the curve. This relationship is also represented in Figure 1. A linear relationship in this same part of the curve may also be obtained by plotting the logarithms of

Fig 3 A represents the heparin cofactor activity of a group of surgical patients who developed no thromboembolic complications. B and C represent the activity of 2 patients who developed venous thrombosis.

the clotting times and the concentrations of thrombin. We prefer to read the concentration of thrombin remaining, after inactivation by the heparin cofactor, directly from the curve after noting the clotting time.

It is obvious that significant determinations fall only within clotting times of 10 to 60 seconds. For this reason the amount of thrombin placed in the original mixture is varied in order that the amount remaining may be accurately determined. Figure 2 shows that a linear relationship exists between the amount of thrombin destroyed or heparin cofactor units and the amount of thrombin placed in the serum. This linear relationship does not hold for larger or smaller amounts of thrombin. The equation representing this curve is also shown in Figure 2. By using either the graph or the equation, percentages of normal cofactor activity may be determined and variations from the normal may be compared.

The test is performed as follows: 0.1 milliliter of inactivated serum is added to 0.8 milliliter of normal saline, 0.1 milliliter (0.01 mgm) of heparin is added and the mixture allowed to incubate for 2 minutes. Ten units of thrombin are then added and incubation is continued for 5 minutes. One-tenth milliliter of a 1.65 per cent fibrinogen solution is quickly added and a stop watch started. The clotting time is determined. The clotting time depends upon the amount of thrombin remaining (Fig 1) in the mixture and since the amount of thrombin

added is known, the amount destroyed by 0.1 milliliter of serum is easily determined by subtraction. The amount destroyed by 1.0 milliliter of serum is determined by multiplying by 10. A heparin cofactor unit is the quantity necessary to inactivate 1 unit of thrombin. Results may be expressed as either heparin cofactor units or as percentage of thrombin destroyed. Since it is sometimes necessary to use larger quantities of thrombin to obtain significant clotting times, it is preferable to express results as percentage of thrombin destroyed compared to the normal.

Heparin cofactor assays were performed on 67 normal fasting individuals. Destruction of thrombin varied from 83.5 per cent to 97.5 per cent with an average value of 92.0 per cent. Although some variation existed from one individual to another, repeated determinations on the same individual never varied more than 2 per cent. Determinations were completed on 22 patients who underwent major surgical procedures. Tests were performed preoperatively and for the most part every other day postoperatively. Of the 22 patients, 20 developed no thromboembolic complications. They also developed little change in the heparin cofactor activity of their blood. There was an average increase of 3.7 per cent. Three of the patients showed reductions of 0.2 per cent, 0.3 per cent, and 0.4 per cent. The other 2 patients, who developed postoperative venous thrombosis, developed reductions in cofactor activity of 5.8 per cent and 15.0 per cent several days prior to the development of a clinically recognized thrombosis (Fig. 3).

Assays were performed on 6 patients with hypoalbuminemia. Three of the patients had cirrhosis of the liver, 2, pyloric obstruction, and 1, malnutrition. Percentage destruction of thrombin was recorded after several determinations as 80.8, 87.5, 84.5, 82.5, 81.6, and 82.2 with an average value of 83.1 compared to 92 for the control group. In the patient with nutritional hypoproteinemia, as the protein de-

pletion was restored to normal, the heparin cofactor activity rose from 82.5 per cent to 92.5 per cent.

SUMMARY

In this small group of patients the significant observations were that there was very little alteration in the cofactor activity of the serum when no thromboembolic complications occurred. On the other hand, when they did occur, in 2 patients, there were appreciable reductions in the cofactor activity. Whether the latter is cause or effect remains to be demonstrated. It obviously will require a survey of several hundred patients to determine the true significance of these findings.

The observation that hypoalbuminemic patients have a consistently reduced cofactor activity verifies the association of the blood albumin and the thrombin inactivating agents. It also suggests one additional reason for correcting a hypoproteinemic state before surgery.

CYTOLOGIC DIAGNOSIS OF CANCER OF THE DESCENDING COLON AND RECTUM

CHARLES L WISSEMAN, JR, M D, HENRY M LEMON, M D, and
KNOWLES B LAWRENCE, M D, F A C S
Boston, Massachusetts

IN recent years exfoliation of neoplastic cells has been noted from many types of malignant epithelial tumors. This method promises to have diagnostic applications particularly for carcinomas arising in internal organs. Although sporadic reports of finding tumor fragments in a variety of body fluids have appeared over a period of many years, it was not until Papanicolaou's work (9) that really serious consideration was given to diagnosis of malignant tumors by cytological examination of human secretions. The vaginal smear technique has had the greatest clinical trial thus far. Diagnosis of cancer of the uterus by means of smears from this site appears most reliable, though the method has been extended to study of secretions arising elsewhere in the body in an attempt to improve early diagnosis of cancer. For example, considerable success has been attained in the diagnosis of lung tumors by examination of either sputum or bronchial aspirations.

Our studies of the past 2 years have centered about the diagnosis of neoplasms in the gastrointestinal tract including stomach, biliary tract, and colon. It is the purpose of this paper to present our experiences with the study of smears taken at proctoscopy and sigmoidoscopy from the large bowel and rectum with special reference to the diagnosis of malignant epithelial tumors.

REVIEW OF LITERATURE

At the time of our preliminary report (12) on the diagnosis of malignant lesions of the rectum and sigmoid colon by cytologic studies of exfoliated cells, we could find only one

reference, that of Altgauzen, reporting the use of fresh smears taken at proctoscopy for the diagnosis of malignancy. However, in this report very little definite information was available on the criteria used by him or the results obtained. Since that time Hunter and Richardson have mentioned the use of cell blocks and smears of rectal discharges for this purpose.

The cytologic study of rectal discharges in the diagnosis of diverse diseases of the large bowel is not new, the first reports dating back to the early part of this century. The most practical use of this technique has been in the rapid differentiation between bacillary and amebic dysentery, especially in military service. A number of studies (2, 5, 6) have appeared with special reference to this problem describing the cytology of stained and unstained preparations in considerable detail.

In more recent years Bercovitz (3, 4) has made a study of the cytology of rectal discharges after saline purges in both normal and a variety of abnormal conditions. It was his conclusion that discharges from normal bowel contained few, if any, cells whereas cells of various types and in variable proportions and numbers were present in many pathological conditions. In fact, in one paper (4) he presented a photomicrograph of "degenerating epithelium" from a case of carcinoma in which as well as could be determined from the illustration, the cells had many of the characteristics seen in those coming directly from malignancies of the large bowel. It is not unlikely that he had observed exfoliated malignant cells without being aware of it.

MATERIALS AND METHODS

Patients selected for the present study included those suspected of having carcinoma, those with diverse gastrointestinal complaints

From the Robert Dawson Evans Memorial Massachusetts Memorial Hospital, and Departments of Medicine and Surgery Boston University School of Medicine Boston Mass. The expense of part of this work was defrayed by Cancer Teaching Grant C1 618 from the United States Public Health Service to Boston University School of Medicine.

and diagnostic problems. While most of the patients were from the wards of the Massachusetts Memorial Hospitals, a number were derived from neighboring institutions and from the private patients of hospital staff members. All patients received at least one sigmoidoscopy, most, barium enemas, and

others, biopsy. In the majority of suspected cases exploration and resection or biopsy were performed giving pathologic confirmation of the diagnosis. Whenever possible, an attempt was made to establish the diagnosis by older conventional methods in addition to the smear technique.

TABLE I — DISTRIBUTION OF CASES AS TO FINAL DIAGNOSIS

	No cases
Carcinoma of rectum	8
Carcinoma of rectosigmoid and sigmoid	13
Carcinoma of colon (other)	7
Carcinoma elsewhere in body	11
Ulcerative colitis	5
Functional bowel disturbance	13
Diverticulosis and diverticulitis	11
Amebic colitis	1
Acute gastroenteritis	2
Miscellaneous	39
Total	110

Patients were prepared for sigmoidoscopy with cleansing saline enemas. Material collected on cotton swabs during the examination was smeared onto glass slides immediately and was fixed in chilled acetone before drying had taken place. If the lesion was visible, smears were taken directly from its surface. In those cases in which the lesion was not visible specimens consisted of exudate and mucus clinging to the bowel wall. Bloody mucus seen coming from above the proctoscope tended to be particularly rich in exfoliated cells. Slides thus obtained were stained by the Papanicolaou technique (8). The diagnosis of malignancy was made upon finding groups or clumps of cells whose characteristics will be described in the following.

CYTOLOGY OF THE SMEARS

The types of cells found in rectal discharges and stools, especially in cases of dysentery, have been described in considerable detail (2, 3, 4, 5, 6). However, since in the present study the method of sampling differed from those previously described and since the emphasis is placed on the diagnosis of cancer, some discussion of cell types and other structures is warranted.

Smears may contain variable amounts of fecal material depending upon the thoroughness of preparation of the patient for examination. Bacteria, yeast cells, spores, vegetable cells and starch granules, and undigested meat fibers may be encountered. Though such objects are usually quite easily distinguishable, on rare occasions a group of cells which are derived from ingested material may cause some confusion.

Mucus is encountered frequently. It is homogeneous in structure, but it may stain in a variable manner depending upon the thickness. Cells may be found imbedded in it.

Squamous epithelial cells are not infrequently found in smears even from the sigmoid to which location they probably are carried on the end of the sigmoidoscope as it is passed from the anus.

Red blood cells are readily recognized (Fig 8). They may be derived from lesions intrinsic in the bowel, or they may appear as the result of instrumental trauma or vigorous swabbing. Lymphocytes, mononuclear cells, and plasma cells may appear in variable proportions and numbers (Figs 7 and 8). Polymorphonuclear cells, though not usually seen in normal smears, may be seen in large numbers in some diseases of the large bowel (as ulcerative colitis) (Figs 2 and 7). Their presence in any numbers is usually significant. Macrophages may be numerous. They are usually large cells containing dark-staining eccentric pyknotic nuclei and may contain vacuoles filled with ingested cells or cell fragments. Karyorrhexis may be prominent with nuclear material represented by numerous small fragments of dark-staining material. Occasionally grouping of the macrophages may occur (5) (Fig 8). Other mononuclear cells of undetermined origin are not infrequent. Eosinophils have been noted in moderate numbers in several cases, though their significance has not been determined accurately. "Ghost cells" and pyknotic bodies may be observed.

The trophozoites of *Endamoeba histolytica* were found in considerable numbers in the one case of acute amebic colitis examined by us (Fig 7). Though the nuclear detail was not as good as is seen in preparations stained with iron hematoxylin, no difficulty was experienced in identifying the parasites in the smears.

The presence of normal or nonmalignant epithelial cells is not unusual. Their number may vary depending upon the friability of the mucosa and the vigor of swabbing (Fig 1). In general, they are not difficult to distinguish from typically malignant cells. The nuclei are round to oval and quite regular in size.

and staining reaction. There is a well defined nuclear membrane. Chromatin is diffusely scattered throughout in fine granules. There

are usually one to three larger dark-staining granules, inconspicuous to moderately prominent. The columnar cells may appear in a

TABLE II — SMEAR READINGS COMPARED TO FINAL DIAGNOSIS

Positive	Negative	False positive	False negative
9	75	1	12
7	6	Questionable smears*	

*In this column the smears read as questionable are listed under positive or negative with respect to final diagnosis

palisaded arrangement when viewed from the side, or they may appear in sheets of a mosaic pattern if viewed from above. Occasionally entire glandular crypts are found more or less intact. In these, large goblet cells may be seen with ease. Drying, pressure during smearing, and degeneration may alter the appearance markedly. In such instances the cells and nuclei may vary in size and shape, and the nuclei acquire a pale homogeneous "washed out" appearance.

Anderson noted the effect of osmotic pressure on epithelial cells causing them to assume distorted shapes. He also recognized that large numbers may be desquamated during certain phases of bacillary dysentery. Manson-Bahr (11), in discussing scrapings from the rectal mucosa in the diagnosis of amebiasis, stated that in his experience normal cells had well defined outline and structure whereas in certain pathologic conditions they were indistinct and poorly defined. He also made note of increased numbers of swollen goblet cells in cases of mucus colitis.

Bercovitz (3) described four main types of cells derived from scrapings of the bowel mucosa (obtained at post mortem): (1) large wedge-shaped cells with granular cytoplasm and large oval nuclei composed of heavy rings and containing granules, (2) tall columnar cells with finely granular cytoplasm and large oval nuclei with heavy rings and containing granules, (3) cells irregular in shape with granular cytoplasm and oval to round nuclei having delicate rings which constitute the nuclear membrane with granules included, and (4) square cells with granular cytoplasm and small round solid nuclei. However, in our stained preparations, cytoplasmic granules were not encountered.

X-irradiation seems to alter the appearance of the mucosal cells. In 1 case of rectal ric-

TABLE III — RESULTS OF SMEARS ON PROVED CARCINOMAS WITH RESPECT TO THE LOCATION OF THE TUMOR IN THE BOWEL

Sigmoid colon	5	4	3
Other (ascending, transverse, etc.)	0	0	7

ture following radiation therapy for carcinoma of the cervix, the cells appeared larger, somewhat more basophilic, with heavy staining nuclei.

In 1 case of chronic ulcerative colitis a group of cells were observed having some of the nuclear changes seen in malignant cells such as increased size and moderately heavy chromatin aggregates (Fig. 2). It is possible that they were merely regenerating epithelial cells under the influence of an inflammatory process, such as we have observed in gastric epithelium.

Cells considered to arise from malignancies occurred either singly or in groups. A positive diagnosis was not made if only single suspicious cells were found. Clumps were composed mainly of cells arranged in an irregular fashion. Occasionally the arrangement was fairly orderly, however, in most of these instances cellular morphology was so characteristic that malignancy could be diagnosed. In a number of tumors removed surgically, smears were made directly from the lesion in order to compare known malignant cells with those found in the sigmoidoscopic smears (Figs. 3 and 4).

In general cells exfoliated from tumors of the large bowel showed similar deviations from normal as have been observed in malignant cells arising from tumors in other parts of the body, namely, great variation in size and shape of both the cytoplasm and nucleus with an increase in the nuclear-cytoplasmic ratio. Malignant cells were frequently observed to be considerably larger than normal mucosal cells, while the nuclei were also greatly enlarged in a majority of cases (Figs. 5 and 6). Occasionally giant nuclei were observed, at times with only a small ring of cytoplasm. Binucleate cells occurred in smears from several tumors. Mitotic figures

TABLE IV—CLINICAL DATA ON PATIENTS WITH SUSPICIOUS SMEARS AND NO PROOF OF CARCINOMA OF BOWEL

Age	Smear diagnosis	Pertinent history	Proctoscopy	Barium enema	Final diagnosis
54	Positive repeat smear questionable	Adenoca of cecum resected 4 years before	Mucosa slightly inflamed with a few bleed ng points	Negative	Committed to mental hospital for paranoid psychosis no evidence of recurrence of tumor
70	Questionable		Granular mucosa at 7.5-17.5 cm from anus with numerous hemorrhages	Negative	Chronic lymphatic leucemia with acute polyn neuritis
65	Questionable	Hypertrophic and ulcerative proctitis 6 years	Indurated rectal ulcer and leukoplakia	Diverticulosis with narrowing of sigmoid and rectum	Biopsy leukoplakia, no evidence of malignancy
43	Questionable	Adenoca of cervix treated with deep x ray and radium 11 months before	Stricture at 15 cm	Not done	Curettage recurrent carcinoma of cervix rectal stricture presumed secondary to irradiation
40	Questionable		Negative	Negative	Acute and chronic alcoholism
67	Questionable	Epigastric pain 9 weeks with 15 Lgm weight loss	One area of granular mucosa	Negative	Peritoneoscopy with biopsy metastatic adenocarcinoma to liver source unknown
62	Repeat smear negative	Sudden onset lower abdominal cramps a few hours before	Negative	Negative	Transient intestinal obstruction secondary to incarcerated hernia

were rare. Two rather distinct types of chromatin arrangement were observed: (1) large to variable nuclei with heavy irregular deposition about the nuclear membrane and large aggregates of chromatin within and (2) large nuclei with diffusely arranged chromatin simulating a fine reticular network. The former was by far the more common. The chromatin tended to take a rather heavy hematoxylin stain. As was expected, gradations between obviously benign and obviously malignant cells were observed. The smears were read as negative, questionable, or positive for malignancy.

RESULTS

The results of this study as it pertains to the diagnosis of cancer of the large bowel are recorded in Tables II and III. In 9 cases of carcinoma the smears were read as definitely positive and in 7 they were read as questionable. Twelve cases of carcinoma were missed. There was 1 false positive result. Six of the questionable smears proved to be from patients without ascertainable large bowel carcinomas although possible sources for abnormal cells were present in most instances (Table IV).

Summarizing these tables it will be noted that in 16 of 28 carcinomas smears were read as positive or questionable, three-fourths of the tumors of the rectum and sigmoid were either correctly diagnosed or suspected on the

basis of the smears whereas all the tumors of the ascending and transverse portions of the colon were missed. In 110 cases there was one false positive and three-quarters of all cases were diagnosed correctly. It is of interest to note that both of the tumors of the rectum that were missed completely were reported by the pathologists as early or low grade malignant changes in rectal polyps. This is not unexpected since there is considerable discussion among pathologists as to what constitutes early malignant change in polyps even in tissue sections. There were also 4 cases of obstructive lesions of the colon, 1 in the splenic flexure, 3 in the sigmoid, all of which had negative smears, and which were proved to be inflammatory in nature. Two of these cases were associated with diverticulosis of the sigmoid.

DISCUSSION

Up to this time two principal methods have been available for the diagnosis of malignancy of the large bowel: namely, (1) radiologically by means of the barium enema and double contrast studies and (2) direct visualization through the sigmoidoscope with biopsy. When the latter is possible, there remains little to be desired with the exception that biopsies, especially of polyps, may be unsatisfactory. At times the sigmoid may be difficult to visualize by means of x-ray examination. In one series of cases (10) 9 per cent of the tumors

of the sigmoid were missed by x-ray examination. This is exemplified by 1 of our patients in whom both the initial barium enema and sigmoidoscopy were negative. Smears taken at the sigmoidoscopic examination however, were read as positive. Subsequent sigmoidoscopy and barium enema both revealed the lesion which was removed surgically and was proved to be an adenocarcinoma of the sigmoid.

In analyzing the results of this study it becomes obvious that the usefulness of this method lies in the diagnosis and confirmation of diagnosis of malignancies of the lower colon that is the rectum sigmoid, and lower descending colon. It should be emphasized that the tumors need not be seen at the time the smears are made for definite tumor cells were found in 5 cases of carcinoma of the descending and sigmoid colon in which the lesions were not visible. X-ray studies failed to reveal only 1 of these. In 1 case of carcinoma of the rectosigmoid, stricture of the rectum prevented visualization of the tumor by any means but rectal swabbings repeatedly revealed the presence of many neoplastic cells (Fig. 6).

The accuracy of the methods available for the diagnosis of malignancies of the sigmoid colon and rectum in this series was as follows: (1) sigmoidoscopic examination 67 per cent accurate; (2) x-ray examination 79 per cent accurate; and (3) cytologic study of smears

Application of the smear technique to other conditions affecting the large bowel has not been investigated fully by us at this time. However observations such as large numbers of polymorphonuclear cells in certain phases of ulcerative colitis, their sparsity in mucous colitis, and the identification of *Endamoeba histolytica* in a case of amebic colitis suggests that routine preparation of smears at the time of sigmoidoscopy may serve as a valuable adjunct to other diagnostic procedures.

SUMMARY

1. A method for the detection of cancer of the large bowel based upon the cytologic recognition of exfoliated malignant cells in smears taken at sigmoidoscopy is described.

2. The cytology of such smears is discussed briefly.

3. The range of usefulness was found to be limited to the rectum sigmoid colon, and lower descending colon where from two thirds to three-fourths of the tumors were detected or suspected on the basis of the smears.

4. In this region the smear method compared favorably with x-ray examination and sigmoidoscopy with biopsy.

5. It was possible to detect malignant cells from tumors which could not be seen through the sigmoidoscope.

6. The use of smears in the study of conditions other than malignant is suggested.

ABDOMINOPERINEAL REMOVAL OF LOW LYING CANCER OF THE RECTUM

FIVE YEAR CURES AND LOCAL RECURRENCES

VERNON C. DAVID, M.D., F.A.C.S., and R. K. GILCHRIST, M.D., F.A.C.S.,
Chicago, Illinois

IN the surgical treatment of low lying carcinoma of the rectum the literature has shown an increasing interest in operations which we consider less radical than the one stage abdominoperineal operation of Miles. In this communication we should like to discuss this problem again from the pathological and anatomical viewpoint as well as from that of the 5 to 10 year cure of the patient.

It seems to us that the principle involved is to determine what surgical procedure gives the patient the best chance for a long term cure and not whether certain operations are technically possible or that continuity of the intestinal tract, however desirable, can be maintained. In the consideration of such a principle, published studies should insist upon *unselected* material, careful pathological consideration of the type of the cancer based on accepted classifications such as those of Broders and Dukes but also on the percentage of involvement of regional lymphatics in cleared specimens, distant metastases, the resectability rate, the operative mortality, and the *five year plus* survival rate. It is only by some such scheme that comparable statistics can be obtained and reasonable conclusions can be drawn.

We have previously reported (2) the 5 to 10 year cures and local recurrences in 167 unselected patients with cancer of the rectum and sigmoid with a resectability of approxi-

mately 75 per cent. A careful study was made of the location of the tumor and lymph node involvement (3). One hundred and twelve of these rectal carcinomas were at or below the peritoneal reflection between the anterior wall of the rectum and bladder, and 55 were in the rectum above this junction and in the lower sigmoid.

We have used as a criterion of malignancy of cancer the involvement by cancer of the regional lymph nodes which we consider a most important factor. While the degree of differentiation of the tumor cells (Broders' classification) is generally accepted to be an index of the grade of malignancy, we believe that the degree of invasion and metastasis is a better one and lacks in large part the fallacy of personal judgment in determining grades of histological differentiation of cancer cells. Dukes' classification is also an important means of grading the malignancy of the tumor and stresses the involvement of the regional lymphatics in grade III, the most malignant grade.

A study of our unselected cases is submitted which indicates the grade of malignancy of the tumors as judged by Broders' and Dukes' classification. These figures show that in the Broders' classification grades I and II in general have better prognoses than grades III and IV but that again regional lymph node involvement plays the important role in prog-

Fig. 1. Anterolaterally the layers of the abdominal wall have been turned forward along a medial cut, posterolaterally, the alae of the ilium have been cut horizontally, together with the iliopsoas muscles and fasciae, posteriorly the sacrum has been transected at the same horizontal level. All of the peritoneum and the subserous tissue have been removed to expose the fascia of the pelvis. Within the lesser pelvis, the organs have been transected, together with reflections of the diaphragmatic fascia, the endopelvic fascia. The vesical, vaginal, and rectal tubes of endopelvic fascia have been freed from their respective viscera and retracted. (Courtesy of Arthur H. Curtis, Barry J. Anson, and Chester B. McVay. *Surg. Gyn. Obst.* 1939, 68: 161-166)

nosis. The Dukes' classification also substantiates this view.¹

The peritoneal reflection from the anterior wall of the rectum to the bladder was selected as a dividing line in our study because of the regional anatomy of the rectum below this point and because in the experience of a considerable group of surgeons interested in this field of surgery the abdominoperineal opera-

tion is regarded as the most radical operation for the removal of the cancer and the tributary lymphatics and therefore the procedure which is most likely to result in a long term cure (4).

The importance of the regional anatomy of the rectum below the peritoneal reflection concerns itself with the fascial and muscular attachments and contiguity of the rectum to the base of the bladder, the seminal vesicles, the prostate, posterior urethra, and vagina in an anterior and lateral plane and to the sacrum and coccyx posteriorly.

This intimate relation of the bowel to these structures allows for early invasion and at

¹Duke's classification as modified by Drs. Kirklin, Dockerty, and Waugh.

Grade A: Extension limited to mucosa.

Grade B: Extension extending into muscularis propria but not perforating it.

Grade C: Extension penetrating through the muscularis propria.

Grade D: Extension extending beyond Br. B. with involvement of lymph

Fig 2 The fascial layers illustrated in Figure 1 have been removed and the viscera excised to a lower level, in order to demonstrate the muscular constituents of the pelvic floor and the relations of these to the viscera. The urethra has been pulled aside to show the course of the levator fibers on its posterior aspect and the nature of the "pubourethral ligament," indicated by an asterisk. (Courtesy of Arthur H Curtis, Barry J Anson, and Chester B McVay *Surg Gyn Obst*, 1939, 68: 161-166)

tachment of cancer of the rectum to structures contiguous to it and for extension through lymphatic pathways where the pectinate line, vagina, prostate, or levator muscles are involved, some of which as the vaginal lymphatics run to the vaginal portion of the base of the bladder or those along the levator muscles to the obturator glands which are difficult or impossible to remove. In this extraperitoneal location of the cancer the encircling bony pelvis makes widespread removal of soft parts around the rectum more difficult than in the case above the peritoneal reflection where there is a well developed mesentery of the bowel containing the lymphatics and where the bowel is freely movable. Not only is it more difficult to perform a radical operation for an intrinsic cancer of the rectum below the peritoneal reflection but the occasional

necessity of finding it necessary to remove part of the base of the bladder, seminal vesicles, the posterior portion of the prostate, a section of the posterior urethra, a part of the vagina or some of the presacral fascia indicates a definite risk of local recurrence. At the same time, this radical approach is important because it increased the resectability rate and resulted in more 5 year cures than a more conservative approach (1). Twenty patients with low rectal cancer of the 112 studied had either presacral fascia, a portion of the base of the bladder, a portion of the vagina, urethra or prostate removed because of involvement by the cancer of the rectum. Seven of these lived more than 5 years. Five of the 20 patients had a local recurrence.

A glance at Table I will show that of 112 extraperitoneal cancers of the rectum which

Fig 3 Relation of fascia propria to rectum and prostate 1, Schematic cross section showing continuation of fascia propria around the rectum and prostate This fascia must be cut to allow separation of the rectum from the prostate 2, Schematic lateral view of the bowel, showing the origin and extent of the fascia propria indicated by dotted line (Courtesy W F Prior Company From Chapter VI, Volume 2, *Surgery of the Rectum and Anus* by Vernon C David in Dean Lewis' *Practice of Surgery*)

were removed by abdominoperineal resection, 51 per cent were alive and free of cancer 5 to 10 years after operation compared to 65 per cent of intraperitoneal cancers of the rectum and lower sigmoid, one-half of which were removed by abdominoperineal resection and one-half by obstruction resection with subsequent establishment of continuity

Comparing the two groups below and above the peritoneal reflection, about the same number had carcinomatous lymph node involvement (61 per cent and 63 per cent) However, below the peritoneal reflection only 37 per cent with node involvement were alive 5 years or more after operation compared to 51 per cent above the peritoneal reflection

In the group below the peritoneal reflection without node involvement, 74 per cent were

alive 5 years or more after operation compared to 90 per cent of the group above the peritoneal reflection

Local recurrence in the pelvis after operation on cancer of the rectum below the peritoneal reflection with involved nodes was 23 per cent as compared to 3.6 per cent in the group above the peritoneal reflection

It appears from these facts that cancer of the rectum below the peritoneal reflection treated by abdominoperineal resection has a definitely lower rate of long term cure and a far greater incidence of local recurrence after operation than in cancer of the upper rectum and lower sigmoid treated either by abdominoperineal resection or obstruction resection It would also appear obvious that any operation on cancer of the rectum which makes a com-

promise with radicality should be avoided. In this connection it is hoped that similar studies of patients treated by other operations which we consider less radical should be published.

A recent article (5) has categorically denied the difference in prognosis after operation in cancer below the peritoneal reflection as compared to cancer above the peritoneal reflection. We suggest some difference in viewpoint. Their conclusions were based on a *selected* group of 137 patients all *graded group II* of Broders' classification. All patients who died during the postoperative period of hospitalization were omitted from their study.

If our figures omitted the patients lost to follow-up, those who died of other causes without recurrent carcinoma and those who died postoperatively (all of which we believe is contrary to sound statistics), 65.2 per cent of the cancers below the peritoneal reflection lived 5 years or more compared to 75 per cent above the peritoneal reflection. Of those having regional involvement of lymph nodes, their method would give us a 5 year survival

TABLE V — COMPARISON OF 5 TO 10 YEAR SURVIVAL RATE IN CASES OF CARCINOMA ABOVE AND BELOW THE PERITONEAL REFLECTION ACCORDING TO GRADE

	55	36 65.4	112	58 51.8

rate of 49.1 per cent below the peritoneum compared to 60 per cent above it.

In their study (5), all cases were omitted involving the pectinate line as well as those in whom the surgeon felt that the operation might be a palliative one. Study of regional lymph node involvement was made largely on fixed specimens by making numerous cross sections, and the percentage of node involvement by this method gave an incidence of 35 per cent below the peritoneal reflection and of 53 per cent above it. This compares with 61 per cent and 63 per cent in our group. While importance of the resectability rate was stressed it was not given. The importance of the height of the cancer above the anal region was stressed and the choice of the peritoneal reflection as a landmark was depreciated.

THE DIAGNOSIS AND REPAIR OF PSEUDARTHROSIS OF THE SPINE

EDGAR L. RALSTON, M.D., Philadelphia, Pennsylvania, and
WALTER A. L. THOMPSON, M.D., New York, New York

THE operation of spinal fusion for any purpose is followed in some cases by the development of pseudarthrosis, or fusion failure (1, 2, 3, 4, 6). This fact is not always recognized in evaluating the end-results of this operation. The fusion operation by whatever technique employed can be expected to achieve the desired therapeutic effect only if it results in solid bone fusion of properly designated spinal segments. Failure to secure fusion then can only mean failure to secure the therapeutic result desired. It is therefore important that we recognize as early as possible in the postoperative course the development of fusion failure so that it may be corrected.

In reviewing all cases of spinal fusion performed at the New York Orthopaedic Dispensary and Hospital during the 10 year period of 1936 through 1945, certain features contributing to the diagnosis of pseudarthrosis are evident and should be emphasized. The original fusion procedures followed the Hibb's technique.

DIAGNOSIS OF PSEUDARTHROSIS

The diagnosis of pseudarthrosis can be made only when the surgeon is aware that the problem of pseudarthrosis does exist and is to be ruled out in each case following operation. The staff at this hospital has realized this problem for many years and has assumed in each case that fusion has failed until proof to the contrary is shown.

Essentially, pseudarthrosis of the spine produces the same symptoms and physical findings as pseudarthrosis elsewhere in the body. However, those as related to the spine are frequently more difficult to elicit. In addition, these findings may frequently be similar to those first presented by the patient preceding spinal fusion.

From the New York Orthopaedic Dispensary and Hospital

The effectiveness of the operation of spinal fusion in the treatment of any of the clinical conditions in which it has been used cannot be stated until we are certain that the procedure really has resulted in fusion of the spine. Sometimes it may be impossible to answer this question until the fusion area has been exposed surgically and direct examination of the bone mass performed. Usually, however, by careful attention to the postoperative history, physical findings, and roentgenographic examination, a close estimate of the state of fusion may be arrived at prior to resorting to such exploration.

1 Local pain and tenderness. Pain and tenderness sharply localized over any fusion area suggest pseudarthrosis. A patient with lumbosacral strain and instability may present these findings preoperatively and we are aware that a successful spinal fusion does not result in relief of symptoms in all such cases even though they have been carefully selected for this operation. However, the patient that continues with low back pain and solid fusion does not show the sharp localization of pain and tenderness over the fusion plate, demonstrable in pseudarthrosis. Tenderness is best demonstrated with the patient in the prone position, completely relaxed. On deep pressure with the thumb, a limited area is found over the fusion plate that is quite tender, with no radiation of pain from this point. Pressure elsewhere along the spine may show minor degrees of tenderness but on returning repeatedly to the involved area, exquisite tenderness is again elicited, at the same point on each occasion.

Local pain and tenderness are commonly found preoperatively in patients with tuberculosis of the spine. At this hospital these patients are maintained postoperatively at complete bed rest until evidence of arrest of the disease is obtained. This arrest of disease is

Fig 1 a, Tuberculosis of the spine involving the first and second lumbar vertebrae. Spinal fusion, eleventh dorsal to fourth lumbar performed on May 22, 1942. b, Further bone destruction and deformity with pseudarthrosis at level of first to second lumbar. Pseudarthrosis repaired on April 28, 1943. c, Further bone destruction and deformity with pseudarthrosis still apparent. Although the defect is quite visible in the fusion plate, this may not always be demonstrable. If it were not, the presence of a pseudarthrosis would still be indicated by the progressive deformity.

determined by clinical and roentgenographic examination and by the return of the blood erythrocyte sedimentation rate to normal. Should the patient at any time preceding or following ambulation develop localized pain in the area of fusion and should local tenderness be demonstrable, pseudarthrosis is suggested, and further study to determine the presence of such is indicated.

Pain and tenderness are especially helpful findings toward the diagnosis of pseudarthrosis following fusion for scoliosis. They are uncommonly present preoperatively and when found after ambulation with all support removed are indicative of fusion failure.

2 *Progression of deformity or disease* Surgical fusion of the spine means that the spine is fixed by a continuous column of bone that allows no motion in any plane of the body throughout the vertebral segments involved. Collapse of vertebral bodies and further anterior angulation in tuberculous disease of the spine is not consistent with solid fusion. It is recognized that angulation may take place before the fusion matures, and in such a case progression of deformity may be noted for some time following operation. However, continued and progressing deformity over a prolonged period of time means failure of fusion. Such evidence of delayed or faulty fusion is especially useful in areas of the spine where the fusion mass itself is difficult to visu-

alize roentgenographically. On the lateral films evidence of further destruction and collapse of the vertebral bodies may be demonstrable, a factor indicating failure of fusion (Fig 1).

Development or progression of paralysis in the lower extremities may also indicate the presence of pseudarthrosis following fusion for tuberculosis, and should always be considered as a possible cause of such, as well as cord compression by tuberculous granulations or abscess uncomplicated by pseudarthrosis. The pseudarthrosis permits continued activity of the disease and so indirectly may contribute to the development of neurological changes in the extremities. Of the 21 patients who developed pseudarthrosis following fusion for tuberculosis during the period of this study, progression of spasticity was prominent in 5, and in them was considered the main clinical feature warranting exploration.

Following spinal fusion for scoliosis, progression of the lateral deformity indicates failure of fusion. Some error must be allowed for placement of the patient for roentgenography and for measurement of the curve. After final removal of plaster jacket any increase in curvature beyond 5 degrees should be regarded suspiciously and failure of fusion should be considered (Fig 2). This loss of correction is even more significant if it can be shown to have occurred at a single intervertebral level.

Fig 2 a, Scoliosis Original curve from the fifth dorsal to second lumbar measured 64 degrees b, Corrected to 32 degrees and fused c, Loss of correction to 43 degrees noted at 9 months postoperative No definite defect apparent by x ray examination Because of loss of correction and localized tenderness, fusion plate explored and pseudarthrosis found at level of seventh to eighth dorsal vertebrae

and not throughout the length of the fusion mass

3 Roentgen examination The usual roentgenographic examination of any fusion area, including oblique as well as anteroposterior and lateral views, may or may not show a pseudarthrosis when such is present. When it is demonstrable it is seen as an irregular line of translucency extending across the fusion plate in one or all films. The immediately adjacent bone mass may show an increase in density. Such a line of fibrous union may extend completely across an interlaminal space with solid bone fusion present across one or both articular facets. This latter may be difficult to demonstrate roentgenographically. In such a case the roentgen examination will indicate failure of fusion while actually fusion is solid. Quite frequently the line of fusion failure will extend across the plate in an oblique direction in both the coronal and sagittal planes with solid bone mass overlapping above and below as well as in front and behind. Such a line cannot be clearly demonstrated by roentgenographic examination, so that the usual views which are taken in this situation mean nothing in determining the presence or absence of pseudarthrosis.

At this hospital in cases of suspected fusion failure roentgenograms are taken in the lateral position with the spine placed first in maximum extension and then in maximum flexion. Such technique has been especially useful in the study of fusion in the lumbosacral spine. When the films are superimposed over a strong light, variation in the height of the intervertebral disc space at the level of the pseudarthrosis is demonstrable, together with variation in the alignment of the anterior borders of the vertebral bodies (Fig 3). In addition, in the flexed position, separation of the fusion plate at the level of the pseudarthrosis may be demonstrable.

4 Exploration In certain cases the diagnosis of pseudarthrosis cannot be made definitely until the fusion area is exposed surgically. It is our feeling that when doubt as to the diagnosis exists and the clinical picture warrants, exploration is indicated. Adoption of such an attitude will mean that some patients will be subjected to exploration that reveals solid fusion. However, a greater number of patients will benefit from such an exploration.

At exploration the fusion mass is exposed through the line of the old incision. If any

Fig 3 a, Roentgenograms taken a year following spinal fusion of fourth lumbar to sacrum. These suggest fusion failure at fourth to fifth lumbar level. b, and c, Lateral views, taken in flexed and extended positions show failure

at both the fourth to fifth lumbar level and the fifth lumbar to sacrum level. Note the differences in height of the disc spaces. Also note difference in alignment of anterior borders of bodies of fourth and fifth lumbar vertebrae and sacrum.

doubt as to the location or the number of defects exists, the entire plate should be explored. The area is carefully exposed subperiosteally. If the defect is wide with interposition of considerable fibrous tissue, the stripping will proceed with difficulty across it. This may not be demonstrable if the defect is narrow. If the defect is quite narrow considerable search may be required before it can be demonstrated. The surface of the plate is frequently quite irregular and each indentation must be thoroughly cleaned of fibrous tissue. The defect is then demonstrable as a thin line of fibrous tissue, with the adjacent superior and inferior borders of bone mass moving slightly with respiration or on pressure with some blunt instrument. Movement even though barely perceptible is always demonstrable and failure to demonstrate this means that solid union is present.

REPAIR OF PSEUDARTHROSIS

The defect in the fusion plate is carefully exposed as described previously. The line is followed across the width of the plate and laterally it will be found to extend into the apophyseal joints. The joint spaces are carefully explored and any remnants of articular cartilage not removed at the primary operation are excised with the fibrous tissue present

If the defect in fusion is wide with free motion across it, the fibrous tissue filling it is excised to a depth of $\frac{1}{8}$ or $\frac{1}{4}$ inch, entirely across the plate. As in the primary fusion, care must always be taken to protect the underlying dura and cord. If the defect is narrow with little motion across it, the surgeon may prefer to limit this excision of interposing fibrous tissue as some degree of fixation is lost through the wide removal of such. At both sides of the midline narrow troughs measuring $\frac{1}{4}$ inch in width and $\frac{1}{4}$ inch in depth are gouged. These are extended across the defect well above and below into healthy bleeding bone. The troughs are then filled with cancellous bone chips obtained either from the fusion mass itself or from the ilium. Chips are also wedged into the joint spaces after these have been thoroughly cleansed of fibrous tissue or cartilage. Over an area extending across the entire width of the fusion mass and several inches above and below the defect bone chips with their bases undetached are reflected. These are fashioned in the caudad mass with their bases attached caudally and in the cephalad mass with their bases attached cephalad. Healthy bleeding cancellous bone is thus exposed underneath. Multiple small free bone transplants are then placed in longitudinal fashion to bridge the line of pseudarthrosis with both ends of each

Fig 4 a, The line of pseudarthrosis is shown, extending across the fusion plate. The articular facets are not represented in this diagram. b, Narrow troughs have been fashioned across the defect, to be filled later with small free bone transplants. Cortical bone chips with bases unde-

tached have been turned up. c, Free transplants are shown wedged underneath the previously reflected bone above and below the defect. d, Longitudinal section showing how the free transplants may be placed in multiple layers and interlocked.

transplant wedged beneath the edge of the bone previously reflected from the plate. Other free transplants may be superimposed in a similar manner. The fusion mass will usually offer a considerable quantity of transplants or they are easily removed from the ilium. The conclusion of the procedure will show a mass of bone transplants wedged onto cancellous bone above and below the defect and extending across it in the longitudinal axis of the fusion plate (Fig 4).

The previously stripped periosteum is allowed to fall over the bed of bone transplants, sutured, and the incision closed. Depending on the indications for primary fusion, the patient is immobilized with a spine brace or a plaster jacket incorporating both thighs and is kept at absolute bed rest for 8 to 12 weeks. A careful search is then made for possible failure of repair. If fusion has been obtained the patient is allowed up with brace or with an ambulatory jacket. If there is suggestion of failure, immobilization in bed is continued for another 4 weeks. If failure is definitely present, another attempt at repair is then advised.

END-RESULTS

During the period of 1936 through 1945, 1,250 patients underwent operation for spinal fusion. Careful follow up study for at least 1 year after operation was carried out in 1,096 patients. Of this group, the diagnosis of pseudarthrosis was made in 182 patients. The diagnosis was confirmed by exploration of the fusion area in 152 patients. In the remaining 30 patients the diagnosis was established only

by applying the standards listed previously, without exploration. In these patients, exploration was advised, but permission was not granted.

During this same period, 23 patients underwent exploration of the fusion mass for failure of fusion, and solid fusion was found. Thus, of 175 patients subjected to exploration, positive evidence of fusion failure was found at operation in the 152 patients remaining or in 86.8 per cent.

One hundred fifty-two patients underwent operation for repair of pseudarthrosis of the spine. All cases have been followed by clinical and roentgenographic examination for at least 1 year. The method of repair which is here described, with minor variations, has been used in the treatment of all patients. Repair was successful primarily in 119 cases, or 78.3 per cent (Table I).

TABLE I — REPAIR OF PSEUDARTHROSIS

Diagnosis at original fusion	No patients undergoing repair of pseudarthrosis	No patients with successful primary repair	Per cent
Scoliosis	51	42	82.3
Lumbosacral instability	51	42	82.3
Lumbosacral instability internal fixation used at primary fusion	23	17	73.9
Tuberculosis	18	11	66.1
Spondylolisthesis	9	7	77.7
Total	152	119	78.3

Of the 33 cases in which repair was not successful, 16 patients underwent a second attempt at repair and this was successful in 13 cases.

SUMMARY

1 The following findings aid in the diagnosis of pseudarthrosis following the operation for spinal fusion (a) localized pain and tenderness, (b) progression of deformity or disease, (c) roentgenographic demonstration of fusion failure

2 In certain cases the diagnosis cannot be established until the fusion plate is explored. We believe that exploration is indicated in every case in which operation did not accomplish the result anticipated

3 By the technique described, repair of pseudarthrosis is successful primarily in 75 per cent of cases

AUREOMYCIN TREATMENT OF URINARY TRACT INFECTIONS

HARVEY S. COLLINS, M.D., and MAXWELL FINLAND, M.D., Boston, Massachusetts

MUCH progress has been made in recent years in the management and cure of many serious conditions along the urinary tract by minimizing or eliminating the factor of infection. The use of acid forming drugs and, more recently, the widespread use of antibacterial agents, particularly the sulfonamides, penicillin, and streptomycin, all of which are excreted into the urine in high concentration and in an active form, have made it possible to limit or eradicate infection in the genito-urinary tract without resort to local instillations. It has thus become possible to minimize the need for many of the manipulations and instrumentations which cause additional trauma and may result in the introduction or the further spread of infections.

Failures of chemotherapy and antibiotics are still the rule, however, in severe and long standing infections, especially when there is interference with the free flow of urine or when there are anatomic defects or localized foci of infection within the urinary tract which constantly predispose to reinfection. In addition, the use of streptomycin in such cases, even when care is taken to maintain an alkaline urine, is all too frequently associated with the appearance and persistence of resistant strains which then render that antibiotic entirely useless.

The introduction of a new antibiotic, particularly one which is effective against most of the types of bacteria found in urinary tract infections, is excreted in the urine in effective concentrations, is relatively nontoxic and can be given by mouth, warrants a careful study of its possible usefulness in this field.

Aureomycin is such an agent and this paper presents a clinical and bacteriologic study of its effectiveness in the types of infections

which are generally refractory to treatment with other agents or which consistently recur after temporary improvement following the use of the antibacterial agents now available.

Choice of patients The patients selected for treatment with aureomycin were all adults and almost all of them had severe and long standing infections which had failed to respond to treatment. Only 1 patient with a previously untreated acute pyelonephritis complicating pregnancy is included. The others all had various underlying defects along the urinary tract and had been subjected to numerous instrumentations and to various operative procedures either for diagnosis, for relief of symptoms or in an attempt to produce a radical cure. Most of the patients were in the older age groups. Only 4 of the patients, however, were hospitalized during the aureomycin therapy, the others were considered to be especially suitable for ambulatory therapy because they were highly intelligent, completely co-operative, and anxious to be relieved of the infection. Most of the ambulatory patients were referred by Dr. Herbert H. Howard, formerly chief of the Urological Service, who kept these patients under close observation both before and after the aureomycin therapy.

Laboratory studies Urinalyses were done frequently before, during, and after the aureomycin therapy and included examination of the unstained and stained sediment for cellular elements and for bacteria. These urine specimens, collected by catheterization in females or after careful local preparation in males, were also cultured on various media and the various types of organisms that grew out were isolated in pure culture and tested for sensitivity to the antibiotic. The concentrations of aureomycin in the urines were determined at irregular intervals either in single voided specimens or, in some instances, in

urine collected over periods of several hours. The methods are described elsewhere (1, 3).

Aureomycin treatment The antibiotic was provided as a powder in capsules, each containing 50 milligrams, and was given by mouth. Most of the patients received 10 capsules (0.5 gm) morning and night for about a week, but 0.5 gram 4 times a day (before each meal and at bed time) was given for varying periods in some of the patients and in almost all of those who were given a second course.

RESULTS

The relevant clinical and laboratory findings, the therapy used, and an evaluation of its effect in each of 16 patients is shown in Table I. In 7 of these patients a second course of aureomycin was given, usually after an interval of 2 weeks, either because the infection was not completely eliminated or because it recurred.

All but 1 of these patients had a chronic and recurrent infection of the urinary tract which, in most instances, was of several years' duration. Almost all of them had a long history of severe complicating factors, such as urinary retention, frequent instrumentations, prostatectomy, urolithiasis, and chronic and recurrent acute cystitis and pyelonephritis. In

almost all instances, one or more chemotherapeutic or antibiotic agents had been used previously without producing prolonged remissions. Thus, the least favorable types of cases were chosen for evaluation of the effects of aureomycin.

The predominant clinical symptoms prior to the aureomycin therapy were dysuria, poor sphincter control, frequency, nocturia, and cloudy urine. Some had had recurrent attacks of severe costovertebral angle pain and tenderness. The urine was loaded with pus cells in every case.

In general, the pyuria diminished markedly during therapy and disappeared entirely in about half of the patients while treatment was still being given. Symptomatic relief occurred at the same time in most instances, the burning on urination, frequency, and nocturia all diminished or subsided.

The urine became highly acid and remained so throughout the treatment. Cultures obtained immediately before treatment usually revealed only a single strain of organism but in those who received a second course of aureomycin, organisms other than those initially present had appeared during or after the first course. The cultures usually became sterile during the aureomycin treatment. In some of

organism isolated in the same patient had the same sensitivity to aureomycin The numbers after "+" and "0" indicate the day after treatment

the patients, however, *Proteus vulgaris* or *Pseudomonas aeruginosa* and in 2 instances *Escherichia coli* either first appeared or persisted during aureomycin treatment. Infection recurred within a few days in most instances, with either the same or with different organisms. The proteus organisms were the most persistent but pseudomonas also could not be eradicated.

Good results of a permanent nature were, therefore, infrequent in these cases of chronic urinary tract infections. Temporary relief, either slight or moderate, resulted in about two-thirds of the patients. The patient with the acute pyelonephritis complicating pregnancy responded promptly with both symptomatic relief and a bacteriologic cure.

Sensitivity of organisms. As seen in Tables I and II, most of the organisms were quite sensitive to aureomycin. Most of them were completely inhibited by concentrations ranging from 63 to 50 micrograms per milliliter, but the strains of proteus and pseudomonas required 125 to 250 micrograms per milliliter for complete inhibition. Partial inhibition usually occurred in one-half or one-fourth of the concentrations which were needed for complete inhibition. It is seen from Table II that the more resistant organisms are the ones

which persisted or appeared in the cultures during and after the aureomycin treatment. All of the strains of the same organism that were isolated from the same patient, however, were equally sensitive to aureomycin. There was no evidence of any tendency for resistant variants to develop during therapy.

Aureomycin levels. The methods available were rather crude (1, 3). The aureomycin activity in the urine that was demonstrated by these methods was equivalent to concentrations of 32 to 256 micrograms per milliliter in specimens of urine obtained during treatment and between 2 and 12 hours after a dose of 0.5 gram. Of interest is the fact that concentrations of 16 micrograms per milliliter, and sometimes more were obtained as long as 48 hours after the last dose and smaller concentrations were demonstrable for more than 72 hours. The errors involved in the methods were such as to suggest that the actual concentrations were considerably higher, since the antibiotic tends to deteriorate rapidly on standing and even during the course of the tests. Blood levels were usually 2 micrograms per milliliter or less but concentrations of 8 micrograms per milliliter were obtained in 1 patient while he was receiving 1 gram every 12 hours.

TABLE II — SUMMARY OF BACTERIOLOGIC FINDINGS IN THE URINE IN RELATION TO AUREOMYCIN THERAPY

Organism	Sensitivity μg-ml	No of patients*	Relation to aureomycin therapy †		
			Before	During	After
<i>Streptococcus mitior</i>	63	1	1	0	0
<i>Klebsiella pneumoniae</i>	5	1	1	1	—
<i>Aerobacter aerogenes</i>	63-100	9 ¹	7	4	3 [‡]
<i>Escherichia coli</i>	63-100	9 ²	11	6	3
<i>Pseudomonas aeruginosa</i>	200-250	4 ¹	3	3	4
<i>Proteus vulgaris</i>	125-250	7 ¹	4	8	9

*Superscripts indicate the number of patients included from whom the same organism was isolated in relation to 2 separate courses of aureomycin

†The figures denote numbers of patients those receiving 2 courses are listed separately in relation to each course

‡Two of these yielded the only strains that required 50 or 100 μg per ml to inhibit.

Toxic effects These were minimal. The most common complaint was looseness of the bowels with frequent (2 to 4 daily), bulky, and soft stools but not true diarrhea. This was more frequent and was accompanied by some nausea and occasional vomiting when doses of 2 grams a day were given. In some of the patients with cystitis, a disagreeable sensation as of something "drawing" or "squirming" in the pelvis was sometimes noted. This may have been related to the high acidity of the urine during ingestion of large doses of aureomycin. There were no other symptoms in these or in other patients, nor was there any laboratory evidence of renal or liver damage or of any toxic effects on the blood. There were no fevers or rashes attributable to the antibiotic.

COMMENT

These cases were chosen deliberately because, with the exception of the patient with acute pyelonephritis, they represent the types of urinary tract infection which are usually refractory to the chemotherapeutic and antibiotic agents that are now available. When all

of the clinical and bacteriologic findings are taken into account, the results in these cases may be considered to be quite satisfactory, although they still leave much to be desired. The results are probably as good as, if not better than, those usually obtained in similar cases with sulfonamides or with streptomycin. Since most of these patients had previously proved refractory to these agents and some were relieved of symptoms and pyuria for the first time in many months while they were taking aureomycin, this agent may prove to be a useful addition to the therapy of urinary tract infections. Aureomycin has several advantages over other agents used in this field in that it can be given by mouth, it is effective against infections with both gram-positive and gram-negative organisms (2) and from present indications it can be given for long periods without significant toxic effects and without giving rise to resistant variants (2, 3). It is relatively ineffective, however, against infections with *Proteus vulgaris* and with *pyocyaneus*.

CONCLUSIONS

Aureomycin may prove to be a useful addition to the list of agents that are effective in the treatment of urinary tract infections and should have further clinical trials in such infections.

ADDENDUM—Since this paper was submitted for publication, more than 50 additional patients with urinary tract infections have been treated with oral aureomycin. One-third of these patients had acute pyelonephritis, cystitis, or both, and all but 1 of these patients were completely cleared of bacteriuria and pyuria. The results in the chronic cases were similar to those noted in the cases presented here.

STUDY ON THE RELIEF OF OBSTRUCTION IN THE COMMON BILE DUCT AND IN THE PAPILLA OF VATER

MILTON W EISENSTEIN, B S , M D , F A C S , Chicago, Illinois

THE problem of obstruction at the terminal end of the common bile duct has been prominent for many years. The surgeon meets this condition all too frequently, and on occasion he is hard put as to know what to do. Those patients who have had cholecystectomy, with or without choledochotomy, and who subsequently develop evidence of obstruction to the flow of bile from the common bile duct into the duodenum have been responsible for much aggravation for the surgeon. The obstructions to be considered at the present time are those resulting from spasm at the papilla of Vater, and from stones or mucous plugs in the common bile duct.

The presence of a sphincter mechanism at the termination of the common bile duct was noted by Oddi in 1887. Careful anatomical studies by Kirk and by Schwegler and Boyden leave little to be added along this line of investigation. Much has been written regarding the physiology of the sphincter of Oddi, reporting the effect of certain drugs upon the state of the sphincter and the duodenum, but with varying and at times controversial results (1, 2, 4, 6, 7, 8, 10-12, 14, 15, 20-22, 25, 26, 32). Various methods have been described and advocated, in an effort to dislodge or dissolve the obstructing factor, be it stone or mucous plug (3, 5, 13, 17, 18, 23, 24, 29, 30). Such obstructions at the terminal end of the common bile duct may be relieved by either surgical or nonsurgical methods. The surgical approach to the problem is obvious, but in many instances reoperation may not be advisable. One may consider several different approaches, namely, an attempt to enlarge the tube through which the obstructing agent

must pass, an attempt to increase the hydrostatic pressure within the common bile duct proximal to the obstructing agent, thereby forcing it into the duodenum, or a combination of the two. The hydrostatic pressure in the common bile duct may be increased by perfusing solutions through a drainage tube or by the administration of hydrocholeretics which usually result in the outpouring by the liver of a large amount of thin watery bile. The terminal end of the common bile duct may be enlarged by the use of certain drugs, in an effort to produce relaxation of the sphincter of Oddi and duodenum, or possibly an actual paralysis of the sphincter and duodenum as will be seen later. Our problem was, therefore, divided into several parts: (a) a study of the effect of certain drugs upon the state of the sphincter of Oddi and duodenum, (b) a study of the site of action of these drugs and, (c) an attempt to duplicate the problem in the laboratory animal as it appears in the human.

Our preparation was similar to that of Kozoll and Necheles (17), Necheles (25) and Crohn and associates (9). Figure 1 illustrates diagrammatically the animal preparation. Dogs with an average weight of 10 kilograms were anesthetized with sodium pentobarbital. Carotid blood pressure was recorded. The pylorus was ligated and gastric secretion was evacuated through a drain. The common bile duct was cannulated *in situ*. One cannula in its proximal end served to evacuate bile. A second cannula, inserted approximately 2 centimeters from the papilla of Vater and pointing toward the duodenum, was connected by a T tube to a constant infusion pump (27) and to a recording mercury manometer. The solutions which were perfused through the common bile duct at a rate of 2 cubic centimeters per minute were evacuated through a tube in the duodenum, 2 to 3 centimeters distal to the papilla of Vater. Following a control

period, the saline perfusate through the distal common bile duct was replaced by the test drug dissolved in 100 cubic centimeters of saline. The time of perfusion with each drug was approximately 10 minutes, after which time saline perfusion was resumed. In an effort to duplicate what may often occur in the human with biliary tract disease, it was decided to maintain the sphincter of Oddi in a state of spasm. This was accomplished by constant slow intravenous injection of a saline solution of prostigmine, at the rate of 0.1 milligram of the drug per hour.

Changes in rhythmic motility and tone of the sphincter of Oddi are graded as + to +++++. + Denotes a diminution of rate of rhythmic contractions but not of their height. ++ Denotes diminution of rate and slight diminution of height of the contractions. +++ Denotes distinct diminution of both and drop of tone. ++++ Denotes drop of tone and abolition of motility, i.e., complete patency of the sphincter. Nontoxic doses of all drugs were employed. The percentage of effectiveness denotes the per cent incidence of relaxation of the sphincter in all experiments with a given drug.

The drugs which may have an effect on the sphincter of Oddi can be grouped into two categories. The group of topic or local anesthetic drugs were considered as being of possible benefit because of their interference with sensory receptors and afferent branches of reflex arcs, with subsequent release of spasm and subsidence of edema (LeRiche and Crohn and associates). The second large group of drugs includes those responsible for smooth muscle relaxation, either by direct effect on the smooth muscle or by abolishing cholinergic nerve action. Many drugs were tested in an effort to find the one which afforded consistently good results. The drugs were administered intraductally in saline solution or they were given intravenously. The following local or topic anesthetic drugs were tested: procaine, nupercaine, butyn, cocaine, metylocaine. The following antispasmodic or spasmolytic drugs were tested: papaverine, trasentin, atropine, homatropine methyl bromide, dibutylene, amyl nitrite, aminophylline, some spasmolytic drugs have also local anesthetic effects, e.g. trasentin.

In the first group of experiments, drugs were tested by means of perfusion through the

Fig 2 Experiment 10, male dog weighing 12 kilograms
Effect of trasentin ++ Response after perfusing 25 milligrams of trasentin through the common bile duct.

+++ Response following intravenous injection of 25 milligrams of trasentin

common bile duct and part of the duodenum. The results were graded as described before. There was a latent period following perfusion of the drugs which varied from a few seconds to 11 minutes from the time of completion of the perfusion. The latent periods, for the same dose of the same drug, varied in the same animal in a number of experiments. However, in most tests the latent periods were rather short. The duration of drug effect also varied in the same animal with the same dose of the same drug. A +++ response may persist for 25 minutes on one occasion whereas another +++ response may persist for 74 minutes. It was also noted that at times a ++ response would last longer than a +++ response, again using the same dose of the same drug in the same animal. Because of the constancy of the dosage and infusion, it must be assumed that these are variations peculiar to the animal being used at the time. The blood pressures, as recorded, did not vary as a result of perfusion of the test solution through the duct. Of all the drugs used intraductally, the only one which gave results consistently was papaverine, which was graded 100 per cent. Atropine and homatropine methyl bromide were graded 50 per cent, procaine 47 per cent, trasentin 44 per cent, and aminophylline 33 per cent, effective. The other drugs tested, nupercaine, metycaine, butyn, dibutylene, sodium nitrite, and cocaine, were found ineffective. The effect of amyl ni-

trite was rather interesting in that a ++ response was obtained by the perfusion of a saline solution of the drug, the perle having been crushed under saline. However, the result could not be duplicated, even when a crushed perle was held to the animal's nose or tracheal cannula.

In the second group of experiments, drugs were used intravenously. The dog preparation was the same as used before. The drug was injected over a period of 10 minutes and its effect, when present, was seen as soon as the injection was completed and frequently even before completion. The latent periods were shorter with intravenous administration. The length of effect varied in this series as it did when the drugs were perfused through the common bile duct. Also, identical doses of the same drug produced effective changes in the intraductal pressure which were either longer or shorter than the changes produced when the same drug was given intraductally. The duration of effect, using the same dose of the same drug in the same animal, varied, for instance, a +++ response persisted for 62 minutes whereas a +++ response persisted for 38 minutes. However, there seemed to be a more constant relation in this series of tests between the degree and the duration of effective response, i.e., the greater the degree of response, the longer the effect. It was also noted that there was a tendency for the blood pressure to drop during the injection of the

Fig 3 Experiment 11, male dog weighing 12.2 kilograms Effect of papaverine +++ Response after perfusing 33 milligrams of papaverine through the common bile duct ++++ Response following intravenous injection of 33 milligrams of papaverine

test drug or during its period of effectiveness. This could be kept at a minimum by administering the drug slowly and in a dilute solution. In this series papaverine was again rated as being 100 per cent effective. Atropine, homatropine methyl bromide and dibutylene were also rated as 100 per cent, the latter having been used only once. Aminophylline was graded 75 per cent, trasentin 66 per cent, and procaine 41 per cent. The remainder of the drugs tested intravenously, nupercaine, metycaine, butyn, and cocaine, were graded 0 per cent.

Several drugs were tested which have been known to increase intraductal pressure and several others whose specific effect had not yet been determined. These drugs also tested the responsiveness of the sphincter of Oddi and duodenum in a number of experiments. Codeine phosphate, given subcutaneously or intravenously, produced an elevation of intraductal pressure, probably as a result of contracting the sphincter of Oddi and duodenum. Demerol was also tested and found to react in a similar manner, although the effect was not as marked. Adanon, which is said to have a morphine like action, produced an increase in the intraductal pressure.

Figure 2 illustrates the effect obtained after the administration of trasentin intraductally and intravenously. Twenty-five milligrams of the drug were perfused through the common bile duct and a ++ response was obtained

which persisted for about 30 minutes. A +++ response was obtained after the intravenous administration of the same dose of drug, persisting for about 25 minutes. It will be noted that there was no lowering of the blood pressure after either test.

Figure 3 illustrates the effect obtained after the administration of papaverine intraductally and intravenously. Thirty-three milligrams of the drug were perfused through the common bile duct and a +++ response was obtained which persisted for about 30 minutes. A similar dose administered intravenously resulted in a ++++ response persisting for 30 minutes. It will be noted here that the blood pressure was not lowered during the intraductal administration of the drug, but that a temporary lowering did occur following the intravenous injection.

Figure 4, in a similar experiment, demonstrates the effect of 1 milligram of homatropine methyl bromide (Maltbie) when perfused through the common duct, and a much more profound and long lasting effect of half of the dose of the drug given intravenously, there was hardly an effect on the blood pressure.

The question of site of action of these drugs soon arose. Because of the fact that the latent periods proved to be shorter following the intravenous injection than following intraductal perfusion of the drug, it was surmised that perhaps the drugs when perfused through the common bile duct, produced their effects after

Fig 4. Dog M, weighing 14 kilograms July 26, 1947. Nembutal anesthesia. Effect of homatropine methyl bromide. Positive effect following perfusion of 1 milligram of homatropine methyl bromide (Maltbie) through common

duct. Very prolonged ++++ effect following intravenous injection of $\frac{1}{2}$ milligram of same drug. Homatropine methyl bromide was a very effective intravenous drug for relaxation of sphincter of Oddi and duodenum.

absorption from the duodenum. A modification of the dog preparation was instituted. In addition to the preparation described, the duodenum was incised on its antimesenteric border, in the region of the papilla of Vater. The papilla was visualized and covered with one end of a soft rubber tube with a lumen of 0.5 centimeter. An inverted U stitch was placed in the rubber tube, brought out through the duodenal wall away from the papilla, and tied gently over a button, thereby anchoring the tube over the papilla. The other end of the rubber tube came out through the incision in the duodenum and drained into a glass jar. Tests with dyes showed that the duodenum had been excluded from the flow of the perfusion fluid and absorption by the duodenal mucosa of solutions perfused through the common bile duct was therefore minimal. Solutions of papaverine, butyn, procaine, traserutin, aminophylline, atropine, and ether, were perfused through the common bile duct and their effects on intraductal pressure recorded. All drugs were ineffective. At the end of each experiment in this series a drug which was known to decrease intraductal pressure was given intravenously as control. It was reasoned that, if several drugs known to be effective when given intravenously had been perfused through the common bile duct and found to be ineffective, and if an effective

result was obtained by a known effective drug given intravenously, we had proved the site of action of these drugs. Figure 5 illustrates an experiment in this series. Solutions of aminophylline, papaverine, procaine and traserutin were perfused through the common bile duct and produced no effective response, whereas the intravenous injection of 50 milligrams papaverine produced a ++++ response. Papaverine, because of its 100 per cent effectiveness was used at the end of three experiments, aminophylline was used once. Both drugs, when given intravenously, proved to be very effective, after no results had been obtained when the drugs were perfused through the common bile duct. This group of experiments led us to believe that whatever good results we had previously obtained by means of perfusion of drugs through the common bile duct occurred as a result of absorption via the duodenal mucosa, rather than by direct action upon the papilla of Vater. These findings corroborated the fact that the duodenum has great absorptive power in spite of the fact that the perfused solutions spent so little time in that organ.

The next phase of our problem was an attempt to duplicate human pathology in the laboratory animal, the production of an obstruction of the common bile duct. The dog preparation was essentially the same as used

Fig 5 Experiment 26, female dog weighing 13 kilograms. Papilla of Vater covered and duodenum excluded. No effective response of intraductal pressure following perfu-

sion of drug solutions through the common bile duct. +++ Response following intravenous administration of papaverine.

in the first series of experiments except for the fact that small gall stones or small pieces of gravel were placed into the distal segment of the common bile duct before the cannula was inserted. Gravel was used in the smaller common ducts whereas gall stones were used in the larger ones. The dog preparation allowed us to use one or both of the methods mentioned earlier in an effort to produce passage of the obstructing agent into the duodenum. We were able to increase the hydrostatic pressure within the common bile duct proximal to the obstructing agent by means of perfusion pressure or by the intravenous administration of decholin, and we were able to produce relaxation of the sphincter by the intravenous administration of the most effective drug tested earlier. Seven dogs were used for this group of experiments. In dog 27, whose kymograph tracing is presented in Figure 6, two gall stones were inserted into the common bile duct and passed rather quickly into the duodenum under influence of the perfusion pressure. The same occurred after another stone had been inserted. However, a third and larger pair was inserted and passage of these did not occur until we had increased the perfusion pressure and had administered 50 milligrams of papaverine intravenously. In dog 4 a stone was placed into the common bile duct, but the hydrostatic pressure was increased by the intravenous administration of decholin. Decholin was given at intervals of 15 minutes and papaverine was given every 30 minutes. The duodenum was opened at the end of about

2½ hours. Examination revealed the stone to be nearly through the papilla of Vater, with about 75 per cent of its mass protruding into the duodenum. If we had waited a bit longer there was every reason to have expected to find the stone entirely within the duodenum. A rather large piece of gravel was placed in the common bile duct of dog 6 and it did not move in spite of decholin and papaverine administered intravenously and procaine perfused through the common bile duct and the duodenum. Obviously the foreign body was too large for the common bile duct to pass. Several insertions of stones were performed in dog 33. These stones passed into the duodenum under influences of the perfusion pressure. A fifth stone did not pass with perfusion pressure alone. Following the use of papaverine, the intraductal pressure suddenly rose and soon dropped, followed by passage of the stone into the duodenum. This phenomenon may be explained by the stone passing along the common bile duct, meeting the sphincter and causing a rise in the intraductal pressure. The pressure dropped and the stone was passed into the duodenum.

DISCUSSION AND CONCLUSIONS

The problem of obstruction at the terminal end of the common bile duct is interesting, but often is difficult to manage. Our efforts have been directed toward the search for a safe, comparatively easy method for removal of these obstructions, and one which will afford a good chance of success. The investigation

EISENSTEIN RELIEF OF OBSTRUCTION IN COMMON BILE DUCT

55

Fig 6 Experiment 27, male dog weighing 14 kilograms Stone experiment. Stones passed into the duodenum twice under influence of the infusion pump Third stone did not

pass into the duodenum after increasing the perfusion pressure, but did pass into the duodenum after second administration of papaverine

divided itself into three parts, namely (a) a study of the effects of certain drugs on the terminal end of the common bile duct, (b) a study of the site of action of these drugs, and (c) an effort to duplicate in the laboratory animal what may appear in the case of stones in the common bile duct when given into the common bile duct or when injected intravenously, would have a relaxing effect upon the sphincter of Oddi. Two large groups of drugs presented themselves for consideration, the local or topic anesthetic group and the antispasmodic or spasmolytic group. Many members of each group were tested and we found that papaverine gave us the most constant relaxing effect upon the sphincter of Oddi. Papaverine worked equally as well given intravenously or when perfused through the common bile duct. Papaverine has been previously tested by other authors and found to give inconstant results, but in our hands it seemed to be the most reliable of all drugs used. This discrepancy lies probably in the fact that the dose used had been too small. Recent laboratory and clinical studies have emphasized the fact that papaverine must be given in sufficiently large doses to produce the desired effect. The local or topic anesthetic group of drugs seemed to be promising early in our study, but as repeated experiments were carried out they seemed to be less reliable than the antispasmodic group. Other drugs gave

verine, but it seemed to us that papaverine proved to be the drug of choice, because of its reliability in producing a prolonged relaxation of the sphincter of Oddi and duodenum. The problem of the site of action of these drugs used was then investigated. We set out to prove whether a drug acted upon the sphincter of Oddi after absorption through the duodenal mucosa, when it was perfused through the common bile duct, or whether it had a direct action upon the terminal end of the common bile duct. By a method of completely blocking the papilla and thereby blocking out the duodenum, we were able to answer this question. It was found that drug solution perfused through the common bile duct and excluded from the duodenal mucosa had no effect upon the sphincter of Oddi, while the same drug had a good relaxing effect on the sphincter of Oddi when given intravenously. This series of experiments leads us to believe that the effect upon the sphincter of Oddi by the drug solutions perfused through the common bile duct was produced by the drug upon the terminal end of the common bile duct. We were also impressed by the marked absorptive power by the duodenal mucosa of a drug solution which was given in a small section of that organ. The final part of our problem remained in an effort to duplicate human

the laboratory animal. Stones of varying sizes and shapes were inserted into the distal common bile duct and various methods were studied by which they could be made to pass into the duodenum. It seemed reasonable to assume that stones would pass if one of three methods were utilized, building up the hydrostatic pressure within the common bile duct, relaxing the terminal end of the common bile duct, and a combination of the two. The hydrostatic pressure was increased by either perfusing solutions through the common bile duct or by the administration of decholin, which resulted in an increased flow of thin watery bile. The terminal end of the common bile duct was relaxed by the intravenous administration of adequate doses of papaverine. We found the common bile duct to vary considerably with individual animals and on several occasions many insertions of increasingly larger sized stones were necessary in order to test our methods. Some of the stones were forced into the duodenum by the infusion pump running at normal speed, whereas other stones did not pass until the perfusion stroke volume had been increased. The experiments wherein the stones did not pass under the effect of the infusion pump but finally passed when papaverine was given, proved quite satisfying to the observer. Careful experiments on patients will have to determine which of the above procedures are applicable to the human and particularly, what perfusion pressure through a drained common duct can be employed.

SUMMARY

1. Certain drugs, when perfused through the common bile duct, can lower the intraductal pressure by their relaxing effects upon the sphincter of Oddi and duodenum.

2. Papaverine seemed to be the drug of choice. It produced the most constant results when given in large enough doses.

3. The drugs used do not act directly upon the terminal end of the common bile duct. When perfused into the common bile duct they exert their effect after absorption through the duodenal mucosa.

4. Obstructions at the terminal end of the common bile duct, produced experimentally by insertion of stones, were relieved by either increasing the hydrostatic pressure within the common bile duct, by relaxing the sphincter of Oddi and duodenum or by a combination of the two. Pressure in the common ducts was increased either by administration of a hydrochologue, or by perfusion through the cannulated distal common duct.

INTRATHORACIC GOITER LOCATED IN THE POSTERIOR MEDIASTINUM

RICHARD H SWEET, M D , F A C S , Boston, Massachusetts

IN spite of the existence of an extensive literature on the subject of thyroid disease, there remains considerable misunderstanding regarding the development and characteristics of intrathoracic goiter. The terms substernal and intrathoracic goiter are often confused and are sometimes considered to be synonymous. An understanding of the anatomical relations of the several types of intrathoracic goiter is of great importance to the surgeon in the differentiation of these terms.

In the majority of cases when a goiter extends into the thorax, the enlarging gland pushes downward and forward so that its lowermost portion lies ultimately in the superior mediastinum just beneath the sternum. It is rare in such a condition for the tumor to lie almost completely within the chest. There is usually a large component of the gland in the neck as well. The term substernal goiter used to designate such an arrangement is only partially correct and to speak of such goiters as being intrathoracic is somewhat misleading. In true intrathoracic goiter, on the other hand, the largest diameter of the tumor lies in the mediastinum below the thoracic inlet. The majority of these lie anteriorly, but in a few cases the mass descends into the posterior portion of the mediastinum, a situation which has rarely been referred to in the literature. Its importance lies in the fact that such posteriorly placed goiters are often erroneously thought to be primary mediastinal tumors, and in the fact that if they become very large they can be removed only through a thoracotomy incision.

Anatomical considerations Posteriorly placed intrathoracic goiters always have a pedicle-like connection with the thyroid gland in the neck, but this attachment is frequently small. They lie at the farthest posterior aspect of the mediastinum against the vertebral column. They tend to press the esophagus to

the right or left but as a rule they do not disturb the relations of the trachea to as great an extent. A slight forward displacement of the trachea, however, is often observed. As they increase in size they enlarge downward and laterally. When they are very large, they encroach considerably upon the space occupied by the upper lobe of the lung on the side where they happen to lie (Cases 5 and 6).

It has been said that an intrathoracic goiter always retains a position anterior to the recurrent laryngeal nerve and to the inferior thyroid artery. This is correct only in the case of those which descend into the anterior mediastinum and are therefore merely substernal. The goiters which enter the posterior mediastinum lie behind these structures. Furthermore, there is an important difference between the two types of goiter, depending upon their relations to the carotid sheath, the innominate and subclavian arteries, the innominate veins, and, on the right, the superior vena cava. Anteriorly placed substernal goiters always descend in front of these vessels. Posteriorly placed intrathoracic goiters, on the other hand, always descend behind them.

The reason for the differences between the anatomical relations of the two types of intrathoracic goiter is a simple one. Substernal and anteriorly placed intrathoracic goiters arise either from the lower poles of the lateral thyroid lobes or from the isthmus. As they enlarge and extend downward, they push the trachea and esophagus posteriorly and laterally and always lie in front of the recurrent laryngeal nerve, the inferior thyroid artery, the innominate veins, the innominate and subclavian arteries, and to some extent the carotid sheath. The fact that posteriorly placed goiters descend behind these structures is explained by the fact that such goiters arise not from the inferior pole of the lateral lobe of the gland but from its posterior and lateral aspect.

Fig 1, left Case 1 Anterior roentgenogram showing marked deviation of the esophagus produced by small intrathoracic goiter with relatively little tracheal displacement

Fig 2 Case 1 Lateral roentgenogram showing slight anterior deviation of the trachea at the base of the neck

The validity of this explanation based upon the site of origin of the goiter in the gland itself is strongly suggested by the findings at operation in 3 of the 6 cases reported. In Case 1 the preoperative roentgenogram showed marked displacement of the esophagus to the left side and only slight displacement of the trachea forward and to the left. At operation, performed through the usual cervical thyroidectomy incision, the lower pole of the right lobe was uninvolved but the goiter, which was relatively small, had arisen from the posterolateral surface of the lobe and had enlarged downward a short way into the mediastinum but definitely behind the carotid sheath and the recurrent laryngeal nerve and inferior thyroid vessels. The situation in this case represented an early phase in the development of a posterior mediastinal intrathoracic goiter. Removal was accomplished easily through the cervical incision (Figs 1 and 2).

Case 2 represents a further stage in the process. In this case the goiter arose from the left lateral lobe and descended posteriorly and to

the left, pushing the esophagus and trachea to the right. At operation it was demonstrated that the enlargement had arisen from the lateral aspect of the left lobe well above the lower pole. It had descended behind the recurrent laryngeal nerve and inferior thyroid vessels as well as the carotid sheath and left subclavian vessels, lodging finally in the posterior mediastinum against the anterior surfaces of the upper thoracic vertebral bodies. It bulged into the left pleural cavity but was relatively easily removed through the cervical incision. In this case the mass was larger and had extended much further downward and posteriorly than in Case 1 (Figs 3 and 4).

Case 3 is of particular importance in demonstrating the origin and anatomical relations of a posteriorly descended intrathoracic goiter. The intrathoracic extension in this instance was unusually large. Upon exploration through the usual cervical incision it was possible to demonstrate that there was no appreciable enlargement of the right lobe excepting for the goiter itself which was almost entirely intra-

Fig 3, left Case 2 Anterior roentgenogram showing moderately large intrathoracic goiter with rather marked lateral displacement of trachea

Fig 4 Case 2 Lateral roentgenogram showing posterior location of the goiter lying upon the upper thoracic vertebrae

thoracic The attachment to the gland consisted only in a relatively thin and narrow strip of thyroid tissue which extended downward behind the great vessels of the neck into the posterior mediastinum where it expanded into a large goiter lying upon the anterior surface of the spine, pushing the esophagus to the left and bulging against the right pleural sac. These relations were more readily demonstrated because of the use in this case of the combined cervical and thoracic incisions (Figs 5, 6, 7, 8)

Technical considerations Almost without exception substernal or anterior intrathoracic goiters can be removed through the usual cervical thyroidectomy incision. This is because by pushing the great vessels and trachea posteriorly during their development they create a space from which they can be enucleated with relative ease by exerting upward traction on the gland while the dissection around and beneath the goiter is being accomplished.

Posteriorly descended goiters, on the other hand, may present a considerable obstacle to

removal through the neck. This is because the space through which they must be extracted is relatively small and because when very large they are almost invariably attached only by a narrow pedicle which occupies a small space at the thoracic inlet. This space is bounded laterally by the first rib, posteriorly by the vertebral column, medially by the trachea and esophagus, and anteriorly by the carotid sheath and the subclavian and innominate vessels. Through this small, rigid-walled aperture it is impossible to extract a very large posterior goiter attached to the gland by only a narrow segment of thyroid tissue (Fig 8). It is necessary in such cases to remove the goiter through a thoracotomy incision. The necessity for using the thoracic approach can be decided on the basis of the size of the tumor mass as visualized in roentgenograms of the chest. In Cases 5 and 6 the necessity for using the thoracic approach was obvious. As in Case 3, the decision to open the chest may have to be made after an attempted removal through

Fig 5, left Case 3 Anterior roentgenogram showing intrathoracic goiter bulging to the right with downward descent to approximately the level of the arch of the azygos vein

Fig 6 Case 3 Lateral roentgenogram showing posterior location of the goiter

a cervical incision has failed. There is no objection in such a situation to turning the patient on his side and removing the mass through a standard thoracotomy incision provided that the anesthetist has taken the precaution to use an intratracheal tube so that positive pressure may be exerted upon the lung. Of the 6 cases reported, the thoracic approach was mandatory in 2 and preferable in 1 case. In the 3 other cases the goiter was small enough to be removed easily through the neck.

Symptoms Five patients complained of cough, in 2 of these the cough was very troublesome. Expectoration was not a factor in any case. Two patients experienced moderate dysphagia as a result of pressure on the esophagus. In 1 there was pain referred to the shoulder on the side where the goiter was. A moderate degree of dysphonia was noticed by 1 patient. One patient experienced no symptoms whatever. The symptoms in all 5 cases in which they were present were mild, but

complete relief resulted from the operation in all cases.

Indications for operation The decision to operate in cases of posterior intrathoracic goiter should be based partly on the presence of symptoms but partly also upon the prediction that progressive difficulty is to be anticipated. An equally important factor is the knowledge that as the tumor enlarges, the technical difficulties encountered in its removal inevitably increase. If operation is performed early, an excision of the mass can be accomplished through the usual thyroidectomy incision. If the goiter exceeds a certain size, however, a thoracotomy becomes necessary for its extirpation. The desirability of early discovery and prompt removal of these tumors is therefore obvious.

CASE REPORTS

CASE 1 A R, MGH No 587155, female, aged 33 years, was admitted to the hospital on November 17, 1947 because of trouble with swallowing. About 18 months previously she had had an attack of acute choking after swallowing a peanut. Since that time

Fig 7 Case 3 Drawing based on sketches made at operation showing the goiter through the thoracotomy incision. Note the relations of the mass to the spine, the azygos vein, and the superior vena cava.

she had had the feeling that there was a lump present behind the upper sternum inhibiting the swallowing of large particles. She had had no vomiting or bleeding. She had a dry cough which she thought was due to pressure. She had lost about 3 pounds in weight during the previous few weeks but was otherwise well. She denied nervousness, increase of appetite, insomnia, intolerance to heat, diarrhea, or any other signs of thyrotoxicosis.

On physical examination no mass could be felt in the neck. The heart was regular, the sounds of good quality, and no murmurs were heard. Blood pressure was 130/85.

Roentgenographic studies showed a mass in the right side of the neck displacing the esophagus to the left (Figs 1 and 2). Her basal metabolic rate was +21 per cent.

An operation was performed on November 19, 1947. The usual curved thyroid incision was made. The pretracheal muscles were separated in the midline and retracted so as to expose the right lobe of the thyroid. The lobe itself appeared to be essentially normal, but arising from the posterior aspect above the lower pole there was a rounded, soft tumor mass about 4 centimeters in diameter, possibly larger, extending downward into the superior mediastinum behind the innominate artery. By getting into the proper plane of cleavage it was easy

to liberate this tumor and deliver it through the wound. In doing this, however, it burst and a considerable amount of fluid was evacuated. From that point on the removal of the abnormal mass was carried out in the usual fashion. At the completion of the operation the layers were approximated with interrupted fine silk sutures. No drainage was used.

After microscopic diagnosis the pathologist reported the tumor to be nodular goiter with hyperplasia and involution. She made an uneventful recovery and was discharged from the hospital in excellent condition 5 days postoperatively with the wound well healed, swallowing well, and without evidence of hoarseness.

CASE 2 H. B., MGH No 610270, male, aged 57 years, was admitted to the hospital on March 8, 1948, because of hoarseness, cough, hemoptysis, asthmatic breathing, and fatigue. He had a prolonged history of asthma. There was some evidence of bronchiectasis on the roentgenogram of the chest, but bronchoscopic examination was completely negative. Roentgen examination, however, showed the presence of a soft tissue mass in the left upper mediastinum deviating the trachea to the right (Figs 3 and 4). Because this mass appeared to be pressing on the trachea and was believed to be contributing to his symptoms, an operation was advised. His basal metabolic rate was -4 per cent.

Fig 8 Case 3 Composite drawing based upon observations of the anatomical relations of the goiter as seen through both cervical and thoracic incisions. Note (1) The tumor arises by a narrow pedunculated attachment from the posterolateral aspect of the right lobe of the thyroid (2) It had descended behind the vessels in the carotid sheath, the subclavian vein and artery, the innominate vein, and the superior vena cava (3) The recurrent laryngeal nerve (not shown) approaches the larynx beneath the uninvolved lower pole of the lobe and anterior to the pedicle of the goiter

The operation was performed on March 19, 1948. The usual thyroid incision was made. The pretracheal muscles were parted in the midline and retracted. By entering the proper plane of cleavage it was possible to palpate downward along the left lobe of the thyroid and the intrathoracic goiter was felt. The tumor arose from the posterior aspect of the thyroid lobe instead of from the inferior pole. It extended behind the carotid sheath posteriorly and lay against the anterior surface of the vertebral column. There were no adhesions so that it was relatively easy to pull it up by grasping it with tenaculum forceps. It was then delivered through the wound and removed, except for a small portion of the lobe which was left behind. The cut edges of the lobe were approximated by means of several fine silk sutures after the vessels were tied. The muscles were then drawn together, the divided platysma edges were sutured, and the skin was closed with silk. No drainage was used.

On pathological examination a microscopic diagnosis of struma nodosa micro et macro folliculare was made.

The patient's postoperative recovery was uneventful and he was discharged from the hospital in good condition.

CASE 3 W K, MGH No 602786, male, aged 43 years, was admitted to the hospital originally for diagnosis and treatment of a very troublesome diarrhea. Roentgen-ray examination of the chest revealed the presence of a rounded mass in the upper mediastinum on the right side, displacing the trachea to the left (Figs 5 and 6). The esophagus was not much deviated. There was slight motion of the mass on swallowing. There were no symptoms attributable to this tumor, but excision was advised on the basis that it should be removed before it became large enough to cause serious trouble. His basal metabolic rate just prior to operation was +4 per cent.

An operation was performed on March 24, 1948. The usual thyroid incision was made in the neck. The pretracheal muscles were parted in the midline and retracted. It was soon discovered that there was a mass extending downward from the posterior surface of the right lobe of the thyroid behind the jugular vein and carotid artery and descending into the thorax posteriorly so as to lie upon the vertebral column. A tenaculum was applied and considerable force was exerted in an effort to pull the tumor up. Blunt dissection with the finger down into the chest as far as could be reached failed to free the mass and it seemed obvious that it could not be delivered

Fig 9, left Case 4 Anterior roentgenogram showing posterior intrathoracic goiter of fairly large size removed through a cervical incision

Fig 10, Case 4 Lateral roentgenogram showing posterior location of the goiter with marked anterior deviation of the trachea

readily through the neck. The cervical incision was therefore closed and the patient was turned on his left side

A standard thoracotomy incision was made on the right side and the chest was opened through the fourth intercostal space. The large bulging goiter could be seen protruding beneath the mediastinal pleura (Fig 7). It extended downward as far as the azygos vein. It pushed the superior vena cava forward and was resting upon the vertebral column. An incision was made in the mediastinal pleura and the goiter was freed of its local fixation, which was quite considerable. In the process of dissection it broke with the discharge of 1 or 2 ounces of watery fluid. An effort was made to get around the proximal attachment of the goiter in order to remove it from below, but it was discovered that there was a medial extension in the region of the trachea and esophagus which could not be reached because it was so high in the neck. On the other hand, the reduction in the size of the tumor and the freeing of its adhesions made it possible to withdraw it from the chest through the neck. It was therefore decided to close the chest wound and to remove the goiter through the cervical incision.

After closure of the thoracotomy incision the patient was put on his back once more. The cervical

incision was reopened and the goiter was delivered with relative ease. It had arisen from the posterior aspect of the gland and not from the inferior pole. It was necessary, however, to remove the major portion of the right lobe in order to get the base of this goiter out. This was done without much difficulty and the wound was once more closed in layers, by means of interrupted silk sutures without drainage.

On microscopic examination the pathologist made a diagnosis of nontoxic nodular goiter, involution, hyperinvolution with cyst formation, and adenoma.

Following operation the patient had periods of slight difficulty with breathing, but his recovery was essentially uneventful and he was discharged from the hospital in excellent condition.

CASE 4 I L, MGH No 600308, female, aged 56 years, was admitted to the hospital on December 4, 1947. Nine months previously she had had the rapid onset of paroxysms of coughing. There was no loss of weight. Her local doctor had discovered the presence of a superior mediastinal tumor which was treated by roentgen therapy with very slight shrinking in size. There was no dysphagia, feeling of pressure, pain, or hemoptysis.

Roentgenographic studies of the chest showed a smooth, rounded tumor mass in the superior mediastinum bulging slightly more to the right than to the

Fig. 11, left. CASE 5. Anterior roentgenogram showing unusually large posterior mediastinal mass arising from right lobe of thyroid, removed through a thoracotomy incision. Deviation of trachea shown.

Fig. 11, right. CASE 5. Lateral roentgenogram showing posterior location of the tumor actually overlying the middle of the vertebral column.

but displacing the esophagus and trachea inferiorly and to the right (Fig. 9 and 10). The mass showed slight pulsation which appeared to be transmitted. It moved upward on swallowing. No calcification was seen within the mass and there was no evidence of bone erosion. Both lung fields were clear.

On December 8, 1937, an operation was performed

CASE 5. A. A. MGH No. 45,419 and 45,463. 43-year-old male admitted to the hospital on April 1, 1933 complaining of paroxysmal cough of three to four months duration. Four months previously a roentgen examination had revealed the presence of a mass in the right upper chest. The mass was removed by thoracotomy with a thoracotomy at the level of

Fig 13, left Case 6 Anterior roentgenogram showing very large posterior intrathoracic goiter arising from right lobe of thyroid, removed through thoracotomy incision

Fig 14. Case 6 Lateral roentgenogram showing posterior location of goiter overlying the side of the vertebral column

An operation was performed on May 3, 1943. A long oblique incision was made across the right chest. The chest was opened by the rib resection technique through the bed of the sixth rib. The tumor appeared to be mediastinal in origin, but it protruded a long distance into the right side of the chest, extending posteriorly as it went. There were no adhesions of the lung. The mediastinal pleura was incised, and the tumor was found to be covered by a network of very large, thin-walled veins. It had a pedicle coming from the base of the neck. After the periphery of the tumor was freed the pedicle was reduced to about 2 by 3 centimeters in size and this tissue felt exactly like thyroid tissue. The tumor was obviously solid. It was immediately apparent that the growth had arisen from the right lobe of the thyroid gland, extending down lateral to the trachea in the chest and behind the subclavian artery.

Clamps were placed on the pedicle and the tumor was removed. The vessels of the pedicle were secured with suture ligatures. The incision in the mediastinal pleura was closed with interrupted silk sutures and the lung was re expanded. The chest wall was closed in the usual manner by means of silk sutures. No drainage was used.

The pathologic diagnosis after microscopic examination was mediastinal thyroid, hyperinvolution.

On the first postoperative day 700 cubic centimeters of air was aspirated from the right pleural space. On the next day he had a period of auricular fibrillation, but this was readily controlled by means of cedi-

land. On the fourth day aspiration of the chest yielded 500 cubic centimeters of deeply blood-stained fluid. His subsequent convalescence was slow but satisfactory and he was discharged from the hospital in good condition and relieved of his symptoms on the nineteenth day following operation.

CASE 6 K C, PMH No 47 374, female, aged 51 years, was admitted to the hospital on March 3, 1947. Roentgen-ray examination during a routine chest survey of all the employees of the company with which she was associated had revealed the presence of an upper thoracic mass. Up to that time she had thought she had no symptoms, but on careful questioning it was quite apparent that she had had in the previous year or two an increasing amount of dry irritative cough and more recently a certain amount of dysphagia.

Physical examination was negative except for possibly a little more dullness in the superior mediastinum than one might expect. Roentgen-ray examination, however, revealed the presence of a smoothly rounded mass in the right upper thorax medially and anteriorly (Figs 13 and 14). The mass measured about 6 by 8 centimeters and was of homogeneous density. By fluoroscopy it showed no evidence of pulsation, but there was a definite tracheal tug with swallowing. The heart and great vessels appeared normal, and examination of the esophagus showed no abnormality. The mass was in contact with the trachea and produced very slight narrowing and displacement of it.

An operation was performed on March 6, 1947. A long oblique incision was made across the right chest and the fourth rib was resected. This incision gave good exposure to the superior portion of the chest and the superior mediastinum. The tumor was very large, extending from the base of the neck down to the right main bronchus. Its lower end depressed the arch of the azygos vein. It lay in the posterior aspect of the chest behind the level of the superior vena cava and did not come at all close to the anterior chest wall. It was obviously a posteriorly placed intrathoracic goiter. It was very vascular, but when the proper plane of cleavage was entered it was readily dissected free. It was necessary in order to start the dissection in the proper plane to divide the azygos vein. The tumor was freed and the large vascular pedicle coming down from the right lobe of the thyroid beneath the clavicle and first rib was secured by means of hemostats and stitch ligatures of heavy silk. In doing this the subclavian artery and vein had to be carefully avoided. No evidence of the recurrent laryngeal nerve could be made out.

After the tumor had been removed and the vascular bleeding points had been secured, the edges of the mediastinal pleura were approximated with interrupted silk, the lung was fully expanded and the chest wall was closed in layers, the silk technique being used.

On microscopic examination the pathologist reported this tumor to be multiple colloid adenomatous goiter.

The post-operative convalescence was uneventful. The wound healed well and she was discharged from the hospital in excellent condition on the seventeenth postoperative day.

CONCLUSIONS

1. In general intrathoracic goiters should be removed not only because of the symptoms they may be causing when the patient is first seen but also because as they increase in size the technical difficulty of the operation becomes greater.

2. In order to plan the operation to the best advantage it is important for the surgeon to distinguish between the anterior substernal goiters and those which lie posteriorly. The former can almost invariably be removed through a cervical incision. The latter, on the other hand, may require a thoracotomy if they are unusually large.

3. The suggestion that the descent of a goiter into the posterior mediastinum is caused by the fact that it happens to arise from the posterior or lateral aspects of the thyroid lobe above the lower pole appears to be a reasonable explanation of this relatively infrequent occurrence.

OUTLET PELVIMETRY

Results in Measuring the Symphysis-Biparietal and Sacral-Biparietal Diameters in 145 Primiparous Women

HERBERT THOMS, M D, and CHARLES B CHENEY, M D, New Haven, Connecticut

THE use of manual methods to determine the size and contours of the bony pelvic outlet is an important obstetrical procedure. The simple palpation of the arch, the tubera ischia, and the coccyx and lower sacrum, even without mensuration, will give to the experienced examiner valuable information. Unfortunately, because of the lack of definite end-points, such as are found in the pelvic inlet and the pelvic midplane, the dimensions of the outlet in terms of diameters are subject to variation due to subjective interpretation. This is true in both the manual and the roentgenologic methods used for this purpose. Having these considerations in mind, the senior author described in 1946(3) a pelvimeter for estimating the symphysis and sacral biparietal distances. From the mechanics of head and outlet relationship it is recognized that the width of the subpubic angle and the shape of the pubic arch are of considerable importance, but, as Allen logically states, "The important point is clearly how close the occiput is allowed to approach the lower edge of the symphysis." Therefore, as an alternative to attempting to determine the subpubic angle and a transverse outlet diameter, the measurement of the symphysis-biparietal distance is recommended. This is the distance within which a normal biparietal diameter cannot approach the lower edge of the symphysis. This distance, as well as the sacral-biparietal distance, can be determined externally by the pelvimeter described previously (3, Fig 7). The crossbar of this instrument is 9 centimeters and, allowing about 0.5 centimeter for the thickness of the soft parts covering the pubic ram in their

medial aspect, represents an average biparietal diameter of 9.5 centimeters, a figure close to the average of 93 millimeters given by Scammon and Calkins. When this instrument is used the patient is brought well down over edge of the examining table - the lithotomy position, the arch is then palpated, by using both hands alternately, as in the manner usually described in textbooks. The course of the ram downward is noted, whether straight or moderately or widely arcuate. The crossbar of the pelvimeter is then passed between the ram and by upward pressure it is brought as near the symphysis as possible. As the crossbar is held in this position, the end of the arm of the pelvimeter is brought to the lower edge of the symphysis and the symphysis-biparietal distance read on the scale. With the crossbar in position the tip of the arm of the pelvimeter is swung posteriorly to rest externally over the tip of the sacrum. The sacral-biparietal distance is then determined from the scale after subtracting 1 centimeter, which represents the thickness of the sacrum.

The 145 women included in this discussion, all primiparas who had been followed in labor, had a roentgen pelvimetric survey of the pelvis according to the Thoms and Wilson (4) technique, which consists of an inlet and lateral film from which the important diameters of the inlet and pelvic midplane may be measured.

The values for the symphysis-biparietal and sacral-biparietal diameters in these women have been determined and the relationship of these measurements to the type of pelvis, to the transverse diameter of the midplane, and to the type of delivery has been noted. For purposes of classification the pelvic classification which we have found of practical value is reviewed, namely

From the Department of Obstetrics and Gynecology, Yale University School of Medicine and the University Service, Grace-New Haven Community Hospital.

- I Dolichopellic type—The transverse diameter of the inlet is less than the anteroposterior diameter
- II Mesatipellic type—The transverse diameter of the inlet is greater than the anteroposterior diameter by no more than 1 centimeter
- III Brachypellic type—The transverse diameter of the inlet is from 1.0 to 2.9 centimeters greater than the anteroposterior diameter
- IV Platypellic type¹—The transverse diameter of the inlet is 3 centimeters or more greater than the anteroposterior diameter

In considering the pelvic arch in relation to the type of pelvis, it would be expected that the dolichopellic type, with its relatively narrowed sidewalls, also would present a relative narrowing of the arch and, therefore, relatively longer symphysis-biparietal and sacral-biparietal diameters. Conversely the brachypellic type would show relatively shorter symphysis-biparietal and sacral-biparietal distances. These diameters in the mesatipellic type should occupy a midposition. These expectations were borne out.

	Average diameter centimeters
Dolichopellic group—45 pelves	
Symphysis biparietal diameter	5.0
Sacral biparietal diameter	8.0
Transverse midplane diameter	9.9
Mesatipellic group—55 pelves	
Symphysis biparietal diameter	4.5
Sacral biparietal diameter	7.7
Transverse midplane diameter	10.3
Brachypellic group—45 pelves	
Symphysis biparietal diameter	4.9
Sacral biparietal diameter	7.6
Transverse midplane diameter	11.0

A further correlation of the narrowing of the pelvic sidewalls, to the pelvic arch is shown by the relationship of the transverse midplane diameter to the symphysis-biparietal diameter in Table I.

OPERATIVE INTERFERENCE

With transverse narrowing of the lower pelvis both in midplane and outlet as evidenced by a relatively increased symphysis-biparietal distance an increased incidence of operative intervention might be expected. This is shown in the type of delivery of these 145 women. We recognize, however, that

¹The platypellic type is relatively infrequent and almost always shows a characteristic of pelvic outlets. In the present group there were no pelvis of this type.

TABLE I—AVERAGE TRANSVERSE MIDPLANE DIAMETER FOR DIFFERENT SYMPHYSIS BIPARIETAL DIAMETERS

Number of cases	Symphysis biparietal	Average transverse midplane
3	2.5	11.1
10	3.0	11.0
2	3.5	10.8
28	4.0	10.4
12	4.5	10.6
58	5.0	10.6
15	5.5	10.1
13	6.0	10.5
1	6.5	9.9
4	7.0	9.5

the indications for operative delivery in primiparas, which includes low forceps, are manifold. Our results show that of these 14 primiparas, in 113 with a symphysis biparietal distance of 5.0 centimeters or less, 44, or 38.1 per cent, were delivered by operation. In 31 women with symphysis-biparietal diameter greater than 5.0 centimeters, 17, or 53.1 per cent, were delivered by operation.

From this study of outlet pelvimetry in relation to the fetal biparietal diameter certain conclusions previously held have become reinforced. The chief of these is that in order to evaluate pelvic capacity, the pelvis must be studied as a whole, that is, inlet, midplane, and outlet measurements must be included. It is probable that outlet constriction rarely exists alone but is accompanied by relative constriction somewhat higher in the pelvis, especially in the midplane. A proper pelvic survey should include roentgen pelvimetry with inlet and lateral views showing pelvic contours and from which dimensions can be measured. Manual palpation of the pubic arch with measurement of the symphysis-biparietal and sacral-biparietal diameters, as outlined here, are useful adjuncts to roentgen pelvimetric procedures.

THE BIOLOGICAL CHEMISTRY OF WOUND HEALING

II The Effect of dl-Methionine on the Healing of Surface Wounds

S ARTHUR LOCALIO, M D , Med D Sc , F A C S , LEE GILLETTE, M D , and
J WILLIAM HINTON, M D , F A C S , New York, New York

IN a previous publication (5) two of the authors showed that the parenteral administration of dl-methionine to protein-depleted rats shifts the curve of wound healing of abdominal wounds toward normal. In that study the healing of the skin was excluded from the experiments.

Healing of peritoneum, muscle, and fascia is primarily a process of fibroplasia. The healing of a surface defect is primarily a process of contraction and epithelization (2, 3). It seemed to us to be of interest to record the effect of dl-methionine on the healing of surface wounds in protein-depleted rats, and to record briefly observations on 2 patients.

MATERIAL

Young white adult male rats of pure Wistar strain, purchased from a commercial breeder, were used in the experiments. The first group consisted of 45 normal control animals. The second group of 23 animals were depleted and rendered hypoproteinemic by means of diet. The third group of 16 animals were depleted and then received dl-methionine. The fourth group of 16 animals were normal controls which received dl-methionine.

METHODS

Under ether anesthesia and using a template, a standard sized area of skin ($r=1$ cm $a=3.14$ sq cm) was excised from the freshly shaven back of the animals. The wounds were traced on cellophane at 4 day intervals. The cellophane image of the wounds was transferred to bond paper and the bond paper weighed on an analytic balance. The weight of the bond paper per square millimeter was previously determined and by a simple factor

weight was translated to size. This gravimetric method of Douglas (4) is far more simple and rapid than the planimeter, and it was found to be satisfactory.

Group 1, normal control animals, were maintained on a basal ration of purina chow pellets, preoperatively and postoperatively.

The animals in Groups 2 and 3 were placed on a diet containing 0.23 per cent nitrogen and consisting of 10 per cent carrot powder, 5 per cent crisco, 3 per cent agar, 1 per cent salt, and 81 per cent moisture. This diet, used in previous studies (5), was found uniformly to render an animal hypoproteinemic within 5 weeks. At the expiration of 5 weeks the animals were operated upon and their wounds measured as those in Group 1. Postoperatively, the animals of Groups 2 and 3 were maintained upon the nitrogen-poor depleting diet. However, the animals in Group 3 received 150 milligrams of dl-methionine subcutaneously daily during the entire postoperative period of observation.

The fourth group of animals were normal animals which received 150 milligrams of dl-methionine parenterally, starting on the first postoperative day and continuing throughout the period of observation. The animals were maintained on a diet of purina chow pellets.

At the completion of the experiments in Groups 1, 2, and 3, heart blood was obtained for total protein determinations.

RESULTS

The results are tabulated in Table I, and shown graphically in Figures 1, 2, 3.

The normal control rats gained an average of 56 grams during the experiment, had a normal blood protein of 6.5 grams per cent and healed in 27.1 days.

The depleted rats lost 106 grams, had 3.9 grams per cent of protein in the blood and

From the Surgical Research Laboratory, The New York Post-Graduate Medical School and Hospital. The research was supported by a grant from the National Institute of Health.

Fig 1 Comparison of healing of surface wounds in normal control (x—x—x) and in hypoproteinemic (•—•—•) animals

healed in a calculated average time of 49.8 days. Actually only 6 of the 23 animals in this group went to the stage of final healing. The others died unhealed. In order to obtain data for mathematical comparison, the healing time of the 17 unhealed animals was calculated by estimating the day of healing according to the normal healing curve and not the healing curve of a protein-depleted animal. Had we used the latter calculation, the average healing time would have exceeded by far the 49.8 days

TABLE 1—SUMMARY OF HEALING OF SURFACE WOUNDS IN RATS

Group No		No animals	Wt start grams	Wt end grams	Change grams	Bl prot gm percent	No healing days	Skin diameter sq cm
1	Normal controls	45	222	278	+56	6.5	27.1	7.6
2	Hypoproteinemic	23	206	100	-106	3.9	49.8	20.5
3	Hypoproteinemic plus 150 mgm methionine	16	219	136	-83	4.0	32.6	6.3
4	Normal plus 150 mgm methionine	16					31.6	5.1
5	Calculated by Du Nouy's equation						31.75	

days recorded. Clinically, the wounds appeared pallid, or, as Thompson, Ravdin, and Frank expressed it, "they appeared as if a local anesthetic had been injected in the tissues."

The protein-depleted rats that received dl-methionine lost an average of 83 grams, the blood proteins averaged 4.0 grams per cent and the wounds healed in 32.6 days. In all of these animals wound healing occurred. In the normal animals that received dl-methionine healing took place in 31.6 days. The healing time of a rat wound the size of our average wounds as calculated by Du Nouy's equation for the healing of surface wounds, is 31.75 days.

Except for the untreated protein-depleted hypoproteinemic group, statistically each series was well grouped as regards healing time, as indicated by the standard deviation from the mean.

DISCUSSION

As expected from clinical observation and from previously published work, the healing time of a surface wound in a protein-depleted animal is prolonged. The healing of surface wounds in protein-depleted animals that received dl-methionine approaches the normal, notwithstanding the fact that the animals were maintained upon a depleting diet and remained depleted according to the level of the

Fig 2 Comparison of healing of surface wounds in hypoproteinemic animals receiving dl methionine (○—○—○) and normal animals receiving dl methionine (●—●—●)

Fig 3 Comparison of healing of surface wound of hypoproteinemic animals (●—●—●) and of hypoproteinemic animals receiving dl methionine (○—○—○)

blood proteins. These results also follow those previously recorded for abdominal wounds.

Localio, Morgan, and Hinton outlined an hypothesis indicating that these results may be due to the fact that dl-methionine supplies necessary sulfhydryl (SH) radicals to the enzymatic activity of the chemical reactions that lead to healing. The present study does not prove that hypothesis. However, it does indicate that abnormal healing in a structure con-

taining concentrations of sulfur (hair and skin) can be corrected in large part by an essential sulfur-containing amino acid.

It is of some importance to emphasize that dl-methionine did not speed the healing of a normal wound. These surface wound experiments are more easily put to test in the human than the experiments on the abdominal wall. We have observed 2 patients whose histories we wish to record briefly.

Fig 4, left Case 1 Patient prior to treatment with dl-methionine

Fig 5 Case 1 Patient 6 months after treatment with dl-methionine

CASE 1 F A, Age 10 years, sustained extensive third degree burns $2\frac{1}{2}$ years prior to our observation. For 1 year at another hospital, several attempts to cover the granulations with skin grafts not only failed but the donor sites failed to heal. During the next year at the New York Post-Graduate Medical School and Hospital, 16 attempted skin grafts failed despite antibiotics, transfusions, plasma, oral and intravenous hydrolysates, and numerous forms of local preparation of recipient area. The blood proteins ranged from 5.6 to 5.8 with a normal albumin globulin ratio. The hemoglobin and red blood cell count were maintained within normal limits, and the hematocrit ranged between 41 and 43. When we were asked to see the patient his weight was 43 pounds.

The patient was placed on 1 gram of dl-methionine 3 times daily for 2 weeks with little observable result. At the same time, furacin was used as a local dressing. The dose of dl-methionine was then raised to 2 grams 3 times daily, and on the ninth day, epithelization for the first time was observed in the wound edges. Therapy was continued for 14 weeks, during which time many of the areas epithelized spontaneously. Three skin grafts were attempted and all remained viable.

Six months later the patient weighed 83 pounds. Wounds were healed. Blood protein was 6.7 grams (Figs 4 and 5).

CASE 2 Male, aged 77 years, entered the Fourth Surgical Division of Bellevue Hospital complaining of chronic ulcers of both ankles of 7 years' duration. This patient had generalized atherosclerosis and moderately severe varicosities of the lower extremities. For 16 weeks he was treated by rest, elevation, and numerous varieties of local dressings. Two separate attempts at pinch grafting of the ulcers failed. When we were asked to see the patient, the ulcer on the right covered an area of 108 square centimeters. The anterior surface of the tibia was exposed and necrotic. The ulcer on the left measured 57 square centimeters. The Achilles tendon was exposed and sloughing. Both ulcers had areas of necrotic muscle and slough at their base. The red blood count was 4.0 million, hemoglobin 12.5 grams. Blood proteins were 5.9 total, albumin 3.8, globulin 2.1. The patient was given 500 cubic centimeters of whole blood and 2,500 cubic centimeters of blood plasma. He was maintained on the general ward diet. Ten days later he was placed on 4 grams of dl-methionine 3 times daily. One week following inception of this therapy, epithelization began at the edge of the ulcers. Because of the huge size of the ulcer on the right it was decided to pinch graft this area. In an isolated area below the ankle, roughly 15 per cent of the grafted area, all grafts failed, elsewhere all grafts remained viable and spread. Ten weeks after inception of therapy the unhealed areas measured 12 square centimeters. This included only an area of exposed necrotic bone and the area below the ankle mentioned. In this latter area, epithelization was proceeding from the borders.

The ulcer on the left was not grafted. It was decided to see if this ulcer could be made to heal by epithelization. Ten weeks after inception of dl-methionine therapy, this ulcer measured 15 square centimeters. Of this, 5 square centimeters was over necrotic Achilles tendon. The patient is still under observation.

We do not offer dl-methionine as a panacea for the healing of stubborn surface wounds. Wound healing is much too complex a process to hope that any one factor will solve its problems. On the basis of our animal experiments and 2 cases, we believe that this easily tolerated, apparently nontoxic amino acid, is worthy of further controlled clinical study.

CONCLUSIONS

- 1 Protein depletion markedly prolongs the healing of surface wounds in rats
- 2 The administration of dl-methionine in spite of continued protein depletion, restores the healing time toward normal
- 3 Dl-methionine does not speed the healing of surface wounds of normal rats
- 4 Two clinical cases are presented which

indicate that dl-methionine may be worthy of trial in stubborn unhealed surface wounds in protein-depleted humans

THE PHYSIOLOGICAL EFFECTS OF CURARE

Its Failure to Pass the Placental Membrane or Inhibit Uterine Contractions

PHYLLIS HARROUN, M D, and CARL W FISHER, M D, San Francisco, California

THE present study was undertaken in an effort to add to our knowledge of the pharmacology of curare and to establish an experimental basis for its use for operative deliveries should the need arise

Several authors have reported the use of curare for cesarean section Whitacre and Fisher (8, 9) reported a series of 285 cases of cesarean sections in which curare was used The drug was given "until there was evidence of respiratory depression" One hundred units of intocostin was the average dose They reported that there was no depression of respiration in the baby Cullen said, "The effect of intocostin on the uterus has not been thoroughly studied A number of patients have been given curare for the purpose of producing abdominal muscle relaxation during cesarean section without any apparent adverse effect on uterus or infant" In 1947, G F V Anson advised the use of curare for poor risk patients "including toxemias of pregnancy, ectopic pregnancy, puerperal hemorrhage, inversion of the uterus" He made no mention of the condition of the babies Later in 1947, T Cecil Gray reported the use of d-tubocurarine in 30 cases of cesarean section Premedication consisted of 1/100 grain of atropine Fifteen

units of d-tubocurarine (a subapneic dose) were injected intravenously, followed by 0.3 gram of a thiobarbiturate, "kemithal" Anesthesia was maintained with cyclopropane in a closed system Respirations were "aided" to prevent hypoxia He reported that the babies were awake and showed no signs of curarization, the uteri contracted normally and vigorously, retching and vomiting were rare, and the patients were awake at the end of the operation

At the University of California Hospital we have had no reason as yet to use curare in deliveries of any type No muscular relaxation should be needed for a classical cesarean section, instrumental deliveries from below are more easily handled by simpler anesthetic techniques However, we believe that the use of curare might be advantageous in certain situations, such as emergency intra-abdominal or intrathoracic surgery in which the delivery of the baby is to be performed at the same time, extraperitoneal cesarean section, and perhaps mid and low forceps deliveries in which relaxation of the perineum with preservation of normal uterine tone would be of help At this institution curare is used in doses which are calculated to produce apnea (4, 5, 6, 7) There is no evidence as to what effect such large doses would have on the fetus or the uterine muscle Therefore, we have investigated the effect of apneic doses of curare on pregnant dogs Although our series is small, the results in all cases are identical For this

TABLE I.—SUMMARY OF RESULTS

Dog No	Total dose of curare (intocostrin) units	Duration of apnea hrs min	Condition of pups	Condition of uterine muscle	Condition of dog during surgery	Postoperative condition	Remarks
1	60	3 35	Breathing and squirming	Contracted normally	Good	Good	One pup given 0.5 c.c. intocostin 1/2 became limp and apneic; c after 1 hour
2	90	2 10	Breathing and squirming	Contracted normally	Good	Good	
3	40	2 10	Breathing and squirming	Contracted normally	Good	Good	
4	40	1 45	Breathing and squirming	Contracted normally	Good	Good	
5	80	1 25	Breathing and squirming	Contracted normally	Good	Good	
6	60	2	Breathing and squirming	Contracted normally	Good	Good	
7	60	3 25	Breathing and squirming	Contracted normally	Went into shock	Good	Shock successfully treated by dextrose.
8	100	3 30	Breathing and squirming	Contracted normally	Good	Good	
9	120	4 50	Breathing and squirming	Contracted normally	Good	Good	
10	80	2 50	Breathing and squirming	Contracted normally	Good	Good	

reason we feel justified in reporting them at this time

Ten pregnant bitches near term were used. Nine of them were premedicated with atropine 0.0006 (gr 1/100), the tenth, due to oversight, was unmedicated. Thirty to 80 units of intocostrin (a dose calculated to produce apnea depending on the size of the dog) were injected intravenously. As soon as relaxation and apnea occurred an orotracheal tube was inserted and attached to a breathing bag and a cylinder of oxygen. "Controlled respiration" with oxygen was instituted and continued throughout the procedure. If the dog began to make respiratory efforts before the puppies were delivered, a subsequent dose of 10 to 40 units of intocostrin was given. An abdominal wall block with 1 per cent procaine with epinephrine was done as soon as the endotracheal tube was inserted, and cesarean section performed. Care was taken that the dogs were completely curarized, limp, and apneic until all the puppies were delivered. Controlled respiration was continued until the curare had worn off and the dog was breathing well with both intercostal muscles and diaphragm.

In all 10 cases the results were identical. As soon as the mother's abdominal wall relaxed it became apparent that the pups were not

curarized, their intrauterine squirming became so evident that it seemed as if they would break out of the abdomen by their own effort. On delivery every one of them (69 in all) breathed, squirmed, and in every way behaved like normal pups, this in spite of the fact that in more than half the cases they were considerably premature. None of them was kept alive for more than 2 months, due to lack of facilities in the animal house, but in no case was there any evidence that their death was caused by the curare the mother had received. In every case the uterus contracted normally with or without the use of ergotrate. In all cases the mothers made uncomplicated recoveries.

The possibility that lack of curarization of the pups might be due to resistance to curare rather than to absence of placental transmission of curare was considered. Four units of intocostrin were injected into the umbilical vein of a lively, breathing pup while it was still attached to the placenta, causing complete apnea in 15 seconds. The pup could not be intubated because of the minute size of the larynx and artificial respiration by squeezing the chest was carried on for about an hour. After 45 minutes a few diaphragmatic contractions were felt, but a little later the heart

stopped. It is probable that our attempts at resuscitation were too rough.

Table I gives a summary of our results.

Although we hesitate to report an isolated case, the results in this instance parallel so exactly the findings in dogs that we believe they should be included.

A hysterotomy and sterilization with curare-nitrous oxide anesthesia were performed on a 19 year old epileptic girl, $4\frac{1}{2}$ months pregnant. A single dose of 200 units of curare was administered 5 minutes after the nitrous oxide anesthesia was begun. The baby was delivered 40 minutes after the administration of curare, and when the patient had been in apnea for 35 minutes. The baby was too small to make any respiratory efforts, but all its normal reflexes (withdrawal, knee jerks, etc.) were present and as active as could be expected in a normal fetus of that size. The mother's uterine muscle contracted perfectly normally. The duration of the operation was 1 hour 40 minutes, the duration of apnea, 1 hour 5 minutes. The baby, of course, was not viable, but the mother made a normal recovery.

CONCLUSIONS

1. Curare in apneic doses in dogs does not pass the placental membrane nor inhibit normal postpartum uterine contractions.

2. The reports of previous workers and our own limited observations lead us to believe that these findings can be applied to human patients.

OBSERVATIONS ON THE MACROCYTIC ANEMIA ASSOCIATED WITH PREGNANCY

TOM D SPIES, M D , Birmingham, Alabama

FOR many years we have been studying nutritive failure in families living in areas in which undernutrition is endemic. We have observed in this large group that many persons develop an anemia secondary to infection or hemorrhage, but it is not with this type of anemia that we are concerned in this paper. This report is concerned strictly with the anemia of nutritional origin. The longer we study nutritional anemia, the more it appears to us that it is always a symptom and that in every instance it is indicated that the cause must be found and eliminated as well as the anemia treated specifically.

The relationship of anemia in the mother and the young infant is close, closer perhaps than has been realized. For a number of years we have been studying the anemia complicating pregnancy, which some call the pernicious anemia of pregnancy. It is a macrocytic anemia with a high color index and it responds to liver, folic acid, or yeast. If the mother is not treated while pregnant, the infant also may have anemia later, especially if the infant's diet is poor in substances which contain folic acid or substances which act similarly. We have been making assays of the folic acid content of the various ingredients commonly used in infants' diets but we are not reporting them or the anemias of infancy at this time. The important thing is to realize that there is an association between anemia in the mother and the early development of anemia in the child and to understand the necessity of administering in many instances, yeast, folic acid, meats and meat products, or various mixtures of these materials. For years it has been recognized that certain infants have megaloblastic anemia and some of these infants have been treated successfully with

liver extract. More recently Zuelzer and others described a syndrome of this type which responds to folic acid therapy. We also have observed that folic acid is effective in this type of anemia in infants and children. The point we wish to stress here is that if treatment is administered to the mother and if the baby is fed a diet containing adequate folic acid or substances acting similarly, anemia of this type does not develop.

MATERIALS AND METHODS

Six patients were selected for study using the following criteria:

1. The patient must have been pregnant within a few weeks prior to the initiation of the study.
2. She must have a macrocytic anemia with red blood cell counts of 2.5 million or less and a color index greater than 1.
3. She must have megaloblastic arrest of the bone marrow.
4. She must have free hydrochloric acid in the gastric juice.
5. She must be untreated or must not have been treated recently enough to interfere with folic acid as a therapeutic agent.

The patients were admitted to the hospital and throughout the course of the study were maintained on a diet which was devoid of meat, meat products, fish, poultry, milk and eggs.

Daily hematologic examinations included white and erythrocyte counts, hemoglobin determinations, and reticulocyte counts. Certified Trenner pipettes were used for both the white and the erythrocyte counts. A Jentz colorimeter was used for determining in grams the hemoglobin content of the blood. The reticulocytes were counted in wet preparations by the use of a modified brilliant cresyl blue solution of Dameshek. Cell volumes were determined frequently on oxalated venous blood by Wintrobe hematocrit tubes. Bone marrow was obtained by sternal aspiration prior to therapy and at the peak of reticulo-

cytosis. Differential counts were made on preparations stained while both supravital and Wright's stains.

After the baseline determinations were completed, the patients were given folic acid by mouth. The course in each of the cases is

illustrated in the following representative case history

C C, a white woman aged 29 years, was admitted to the hospital 9 days after the birth of her sixth child. At this time she complained of loss of appetite, weakness, and diarrhea.

Her illness began 7 years previously, after the birth of her second child, with gradual loss of appetite, intermittent diarrhea, and loss of strength. At intervals throughout her third, fourth, and fifth pregnancies, she lost her appetite, lost strength, and had diarrhea and burning of the tongue. Two months prior to her admission to the hospital and during the seventh month of her sixth pregnancy, she lost her appetite, developed diarrhea, and her mouth and tongue became so sore she could eat very little food of any kind. The nutrients supplied by her diet during this time are shown in Figure 1. Her diet, which consisted chiefly of foods assayed for folic acid by Angulo and Spies, was also low in folic acid. She became so weak she stayed in bed all the time and for 6 days following the birth of the child she was too weak even to feed herself. She was then brought to the hospital in an ambulance.

As can be seen in Figure 2, her blood values on admission were: red blood cells, 1.50 million, hemoglobin, 6.6 grams (43 per cent), reticulocytes, 2.6 per cent. She was given 10 milligrams of folic acid daily by mouth. The third day after therapy was initiated, she said she felt much stronger than she had for many months, her tongue ceased burning, her desire for food returned, and she ate most of the food offered. On the fifth day of therapy, the reticulocytes rose to 22.7 per cent. Her diarrhea subsided at this time. Her appetite and strength continued to improve and 10 days after therapy was initiated she began walking around the ward and asked to go home. She was kept on folic acid therapy for 78 days during which time she gained 17 pounds in weight. At the end of this time she was instructed as to the foods she should eat and discharged from the hospital. At this time her blood levels were: red blood cells, 4.20 million, hemoglobin, 11.5 grams (75 per cent), reticulocytes, 0.8 per cent.

In the 2 years since she was treated, her diet has been much more adequate than it had been previously (Fig. 1). She has had no recurrence of symptoms and her blood values are: red blood cells, 4.07 million, hemoglobin, 13.2 grams (86 per cent) (Fig. 2).

DISCUSSION

In this clinic we have made many studies on the specificity of the folic acid molecule

(2, 4). Various fragments of the molecule are ineffective when given alone or in any combination. The change of the glutamic acid to aspartic acid also makes it ineffective. Folic acid either in its conjugated form or in its free form is effective in producing reticulocytosis, an increase in white blood cells, hemoglobin, red blood cells and platelets in persons who have pernicious anemia, nutritional macrocytic anemia, and the macrocytic anemia of pellegra, pregnancy, and sprue (3, 5). Folic acid should be considered a member of the vitamin B complex, as are thiamine, niacin, and riboflavin. The author believes that the pregnant woman should have 2 milligrams of folic acid daily during the latter months of pregnancy.

SUMMARY AND CONCLUSIONS

1. The megaloblastic anemia of pregnancy, infancy, and early childhood often can be prevented by treating the mother in the late stages of pregnancy with substances having an anti-anemic effect. (If this is not done and if the infant develops megaloblastic anemia, it eventually can be relieved by the administration of folic acid.)

2. It is recommended that this anemia associated with pregnancy be prevented by the administration of 2 milligrams of folic acid daily during the latter months of pregnancy. In a few instances 5 milligrams are required.

PRIMARY SPLENIC PANHEMATOPENIA

ROBERT W HEINLE, M D , and WILLIAM D HOLDEN, M D , F A C S , Cleveland, Ohio

IN 1944, Doan first used the term splenic panhematopenia to designate a syndrome characterized principally by splenomegaly, panhyperplasia of the bone marrow, and varying degrees of anemia, neutropenia, and thrombocytopenia. His investigations, which ultimately led to the separation of splenic panhematopenia from other splenic syndromes, were first reported in 1939. In the original report, Wiseman and Doan (9) described 4 patients with a chronic neutropenia which was believed to be caused by sequestration and destruction of neutrophilic granulocytes within the splenic sinusoids. The 4 patients underwent splenectomies with restoration of the blood picture to normal and a subsequent report in 1942 (10) stated that the patients had remained in good health. The 4 original patients displayed some anemia and thrombocytopenia as well as neutropenia and in the 1944 report (2) which included additional patients, the term primary splenic panhematopenia was applied to the syndrome. In 1946, Doan and Wright further divided the syndrome into primary splenic panhematopenia on a congenital or familial basis and splenic panhematopenia secondary to some constitutional pathologic process which disturbed splenic physiology. The primary type of splenic panhematopenia may occur as a chronic relapsing disease with intermittent episodes of hemoclastic activity or as a relatively acute disease characterized by prostration and a rapid depression of the cellular elements of the blood. The secondary acquired form of panhematopenia has been observed in Hodgkin's and Gaucher's diseases (3).

Based principally on the results of epinephrine tests, supravital stained preparations of freshly excised splenic tissue, and the histologic appearance of the bone marrow, Doan and his associates have concluded that the hematologic alterations observed in splenic panhematopenia are due to sequestration of

erythrocytes, leucocytes, and thrombocytes within the splenic sinusoids and the destruction of these elements by reticuloendothelial macrophages. In the majority of Doan's patients the subcutaneous administration of 0.5 to 1.0 cubic centimeter of epinephrine produced a significant elevation of the number of circulating erythrocytes, leucocytes, and thrombocytes. Supravital stained preparations of splenic tissue demonstrated increased phagocytic activity by the clasmatocytes. Bone marrow studies consistently displayed a myeloid hyperplasia and, in many instances, erythroid and megakaryocytic hyperplasia. The authors concluded that congenital hemolytic anemia and idiopathic thrombocytopenic purpura could be included in the same syndrome.

Moore and Bierbaum reported a patient with splenic neutropenia treated successfully by splenectomy. They concluded from supravital staining of fresh splenic tissue that excessive phagocytosis of leucocytes by splenic clasmatocytes was the cause of the neutropenia.

Muether, Moore, Stewart, and Broun did not observe excessive phagocytosis of leucocytes in the spleen in 1 patient. It was not stated, however, whether the microscopic observations were made on supravital stained tissue or fixed sections.

Rogers and Hall reported a patient with splenic neutropenia which could not be explained on a basis of splenic phagocytic activity. Fixed sections of the spleen were studied. In this patient a chronic hepatitis diagnosed by means of a liver biopsy was present. No other patient thus far reported has had any associated or coincidental hepatic disease.

During the past few years, the diagnosis of primary splenic panhematopenia has been made in 7 instances at the University Hospitals of Cleveland. All of the patients have been subjected to splenectomy. One patient died after operation and a postmortem examination was performed. Some of the observations made upon these patients are at variance with those of Doan and his associates. Our

studies offer no support to the hypothesis that the hematologic changes observed in this disease are due to excessive sequestration and phagocytosis of the cellular elements of the blood in the spleen.

The clinical manifestations of primary splenic panhematopenia are variable and depend to a large extent upon the degree of anemia, neutropenia, and thrombocytopenia present. The patients may complain of lassitude, palpitation, and fever. Oral ulceration and indolent ulcers of the lower extremities may be present. Purpura or icterus may or may not be present. Splenomegaly has been present in all but 1 of the patients herein reported.

The peripheral blood shows varying degrees of anemia, neutropenia, or thrombocytopenia or any combination of the three, although neutropenia has been the outstanding feature of our cases. Reticulocytosis and an increase in hemogenous bilirubin as measured by the indirect van den Bergh reaction have been observed in some patients. None of the patients thus far reported here or elsewhere has demonstrated spherocytosis.

Although the exact mechanism producing a reduction of erythrocytes, granulocytes, and thrombocytes in the circulating blood cannot be definitely stated, there is little doubt that this syndrome is separate and distinct from malignant neutropenia, hypoplastic anemia, aleucemic leukemia, Banti's syndrome, and Still's disease.

CASE 1 E D, 42 years old, white, single female was first admitted to University Hospitals on Janu-

ary 28, 1942, when a diagnosis of diabetes insipidus was made and the symptoms were well controlled by administration of pitressin. Congenital absence of the right radius and partial absence of the left radius were demonstrated by roentgenologic examination. Blood findings at that time (Table I) were not striking. She was readmitted on May 25, 1943, complaining of unsteadiness, vertigo, and paralysis of the left hand. She recovered rapidly from these symptoms and a diagnosis of thrombosis of a small vessel of the right cerebrum was made. Again, blood findings were not remarkable. On this admission, roentgenologic examination of the chest revealed streaky, nodular shadows scattered throughout both lungs and the roentgen diagnosis was fibrosis which might have resulted from atypical pneumonia or sarcoidosis. Her next admission was on August 27, 1944, at which time the spleen was palpably enlarged. At this time the blood showed definite anemia and leucopenia as shown in Table I. Roentgenologic examination revealed the urinary tract and skull to be normal. A diagnosis of splenomegaly and possible sarcoidosis was made. The radiographic appearance of the lungs had not changed in 16 months. Her last admission was on December 26, 1944, when she entered complaining of drenching night sweats for 2 months, worse during the preceding 10 days. She claimed to have sustained a loss of weight of 14 pounds in the preceding 20 days. She had experienced dyspnea and orthopnea. Examination revealed a harsh systolic murmur over the left side of the sternum. The spleen extended 6 centimeters below the costal margin. The liver was palpable 1 to 2 centimeters below the costal margin. On January 2, 1945, a petechial type of purpura appeared over the entire body and the temperature rose to 38.5 degrees C.

The blood findings are shown in Table I. A sternal marrow aspiration was performed and revealed the nucleated cell count to be 139,750 per cubic millimeter, the erythrocyte count 1,840,000 per cubic millimeter, and the hemoglobin 6.5 grams per 100 milliliters. The differential count on the marrow

content was neutrophils 10 per cent, eosinophiles 30 per cent, basophiles 0, unsegmented neutrophils 76 per cent, metamyelocytes 76 per cent, myelocytes 138 per cent, myeloblasts 16 per cent, lymphocytes 02 per cent, monocytes 0, normoblasts 316 per cent, erythroblasts 326 per cent, and megakaryoblasts 10 per cent. Fifteen cells in mitosis were seen while counting 500 nucleated cells. These were about evenly divided between red and white cells. The granulocyte-nucleated red cell ratio was 053 - 100. There were many megakaryocytes present. The marrow was interpreted as showing increased activity, with all elements participating, and with an especial increase in the nucleated red cells. Other laboratory findings included an icterus index of 16 units, normal bleeding and clotting times, and a normal fragility test (044 per cent to 036 per cent saline with an identical control). A second icterus index on January 4, 1945, was 13 units. The serum bilirubin was 16 milligrams per 100 milliliters. The van den Bergh reaction was weakly positive, direct delayed. There was no increase of urobilinogen or urobilin in the urine as determined by qualitative tests. The reticulocyte count as shown in Table I was 27 per cent.

Splenectomy was performed on January 6, 1945. The spleen was greatly enlarged and was adherent laterally to the parietal peritoneum. It weighed 888 grams and measured 23.5 by 10.0 by 6.5 centimeters. Examination of imprint preparations with the supravital stain (Janus green and neutral red) and Wright stain failed to reveal the presence of any phagocytic clasmatocytes. Examination of fixed tissue sections stained with hematoxylin and eosin revealed fibrous bands adherent to the outer capsule. The connective tissue in the substance of the spleen was not increased in amount. Follicles were numerous and relatively large, many having distinct secondary centers, some of which showed hyalinization and degeneration. The pulp contained lymphocytes, large mononuclear cells and erythrocytes in usual numbers with a distinct increase in the number of eosinophiles. The oxidase stain revealed the presence of a large number of cells containing oxidase positive granules. Throughout, there were many plasma cells, and large mononuclear cells with acicular, relatively large nuclei. Mitoses were observed and there were some nucleated red cells. Sections treated with potassium ferrocyanide and hydrochloric acid showed throughout the pulp masses of blue material indicating the presence of iron. The diagnosis was splenomegaly with myeloid metaplasia and follicular hyperplasia.

Following operation, there was a steady rise in temperature. The blood pressure fell to very low levels and the patient died on the second postoperative day. Only one postoperative blood examination was done as shown in Table I. Autopsy was performed and the following diagnoses made: chronic interstitial

pneumonitis, bilateral, marked, chronic encephalitis, marked in hypothalamus, congenital defect in the membranous portion of the interventricular septum, covered by septal leaflet of the tricuspid valve. The disease in the lung was definitely considered not to be the result of tuberculosis or sarcoidosis. It was of an inflammatory nature which might have been the result of an atypical pneumonia, although there was no proof for this. There was marked generalized hyperplasia of the bone marrow throughout. It appeared that the cause of death was right heart failure associated with the pulmonary fibrosis.

CASE 2 H. H., 31 years old, white female was admitted to University Hospitals on July 28, 1942, with a chief complaint of "canker sores" in the mouth, which had occurred intermittently every 3 to 4 months during the preceding 15 years. She also noted increased sensitivity to minor infection, stating that small cuts and injuries healed slowly and remained inflamed for long periods of time. Physical examination revealed a well developed, obese, white woman not acutely ill. There was a deforming scar on the lower lip where one of the ulcers had been removed for biopsy at another hospital. Throughout the buccal mucosa were several small ulcers varying in size from 1 to 5 millimeters in diameter. Her gums bled slightly after she brushed her teeth. Small, nontender submental lymph nodes were present. The spleen was palpable 2 centimeters below the costal margin in the left midclavicular line.

Blood findings on several occasions prior to the subsequent splenectomy are shown in Figure 1. Sternal marrow aspiration was performed with the following results: total nucleated elements, 37,150 per cubic millimeter, erythrocytes 4,780,000 per cubic millimeter, hemoglobin, 12.5 grams per 100 milliliters, neutrophils, 21.8 per cent, eosinophiles, 40 per cent, basophiles 0, immature neutrophils, 40.8 per cent, myelocytes, 70 per cent (all ages and varieties), myeloblasts, 12 per cent, lymphocytes, 80 per cent, monocytes, 18 per cent, normoblasts, 13.2 per cent, erythroblasts, 20 per cent, megakaryocytes, 0, plasma cells, 0.2 per cent, and megakaryocytes, 0. The granulocyte-nucleated red cells ratio was 55:100. This was interpreted as representing an active marrow with an increase in the cells of the granulocyte series. An epinephrine test was performed, the results of which are shown in Figure 2. Following the injection of epinephrine the spleen was no longer palpable and the pulse rate increased. Other laboratory data included a blood platelet count of 75,000, reticulocytes, 0.1 per cent, bleeding, coagulation and clot retraction times, normal. Splenectomy was recommended but the patient wished to consider the matter and was discharged on August 3, 1942.

Fig 1 Patient H H Hematologic data before and after splenectomy and follow up
One hundred per cent hemoglobin equals 15.6 grams per 100 milliliters

She was readmitted on September 15, 1942. The mild anemia, marked neutropenia, and thrombocytopenia persisted. She had continued to have crops of small ulcers on the oral mucous membranes. On this admission a fragility test showed beginning hemolysis at 0.48 per cent saline with complete hemolysis at 0.32 per cent saline. Control showed values of 0.46 per cent and 0.32 per cent. The icterus index was 5 units. Urobilinogen and urobilin in the urine were not increased as determined by qualitative tests. A diagnosis of primary splenic neutropenia was made and splenectomy was performed on September 17, 1942. Five hundred milliliters of whole blood were administered at the time of operation. The spleen weighed 280 grams and measured 16 by 9 by 4 centimeters. Supravital preparations (Janus green and neutral red) and Wright stained imprints were examined with care and an unusual number of phagocytes could not be demonstrated. Occasional phagocytic cells were present, always containing erythrocytes. Sections stained with hematoxylin and eosin likewise did not demonstrate any unusual phagocytosis. The follicles were large and numerous, and many showed prominent secondary centers. The diagnosis was follicular hyperplasia of the spleen.

Immediately following splenectomy, there was a marked increase in the number of granulocytes, erythrocytes, hemoglobin, and platelets (Fig 1). It is of interest that the ulcers in the mouth healed within 4 to 5 days after splenectomy. A urinary

tract infection, present from the 15th to the 24th day after splenectomy, was treated successfully with sulfathiazole.

During a follow-up period of 140 weeks there was considerable fluctuation in the number of neutrophils and lymphocytes in the peripheral blood, although the neutrophils remained above preoperative levels. It was noted that when mild infections were present, the neutrophils increased in number. Whether this was true before splenectomy cannot be stated. Occasionally a small ulcer appeared in the mouth, but it never required more than a single treatment with silver nitrate. She gained a considerable amount of weight and felt well. The red blood cell count and hemoglobin levels were a little higher after operation than before and the platelets were present in considerably increased numbers. A small number of target cells were present on the blood films. From Figure 1, it can be seen that there tended to be an inverse relationship between granulocytes and lymphocytes during the entire period of observation following splenectomy.

CASE 3 Patient M B, 36 years old, unmarried, white female, was admitted to University Hospitals on August 13, 1942. Her complaint was "tiredness in the legs, especially on climbing stairs, and a feeling of fullness in the abdomen, especially after eating a full meal." These symptoms had been present for about a year. She stated that at about the time of onset of symptoms, while running in the dark, she struck a wire which was strung about waist high. She was catapulted over the wire and experienced severe pain in the left upper quadrant during the following day, and milder pain for a week. She

Fig 2 Patient H H Epinephrine test

Fig 3 Patient M B Hematologic data before and after splenectomy and follow up, 100 per cent hemoglobin equals 15.6 grams per 100 milliliters

gained about 5 pounds in weight "immediately" and remarked that her dresses felt tight. She added, further, that the gain in weight was limited to the abdomen. She did not consult a physician. Physical examination revealed a well developed and nourished patient who did not appear acutely ill. There was no enlargement of the lymph nodes. A harsh systolic murmur was heard over the cardiac apex. The spleen was greatly enlarged, extending to the umbilicus inferiorly and to the mid-line medially. The remainder of the physical examination was within normal limits. Laboratory examination revealed urine to be normal. Blood findings prior to operation are shown in Figure 3. The icterus index was 7.0 units, and the erythrocyte fragility test showed beginning hemolysis at 0.46 per cent saline and complete hemolysis at 0.34 per cent saline with a control having values of 0.42 per cent and 0.30 per cent. A repeat test showed beginning hemolysis at 0.46 per cent with complete hemolysis at 0.36 per cent with a control having values of 0.40 per cent and 0.32 per cent. Bleeding, coagulation, and clot retraction times were within normal limits.

On August 20, 1942, the urine contained a slightly increased amount of urobilinogen and urobilin. Roentgenologic examinations of the abdomen and gastrointestinal tract were normal except for the presence of the enlarged spleen. The basal metabolic rate was plus 19. On August 14, 1942, a sternal marrow biopsy was performed. Examination of imprint smears stained with Wright's stain and fixed sections stained with hematoxylin and eosin revealed generalized hyperplasia with marked red cell activity. There was a marked reduction in fat and the ratio of nucleated red cells to granulocytes was increased. The differential cell count on the marrow imprints showed percentages of: neutrophils 62, eosinophils 0.4, basophils 0.4, unsegmented neutrophils 13.2, myelocytes 9.2, myeloblasts 1.6, lymphocytes 3.0, monocytes 0, normoblasts 54.0, erythroblasts 10.6, and megaloblasts 1.4. The granulocyte nucleated red cell ratio was 0.47:1.00.

A diagnosis of primary splenic neutropenia was made and splenectomy was performed on August 24, 1942. At operation the spleen appeared to be "five times" its normal size. The patient received 900 milliliters of citrated blood on the day of operation. The spleen weighed 1800 grams and measured 29 by 19 by 5 centimeters. A supravital preparation (Janus green and neutral red) was made and an extensive search made for phagocytic cells. Few such cells could be found and those present contained erythrocytes. Phagocytes containing granulocytic cells could not be demonstrated. Imprint smears stained with Wright's stain and fixed sections stained with hematoxylin and eosin likewise failed to reveal any unusual phagocytosis. The final diagnosis was hyperplasia of the spleen without other histologic abnormality.

Rapid recovery followed the splenectomy. Symptomatic improvement was marked and has continued to the present time. The hematologic findings are shown in Figure 3. It will be noted that immediately following operation, the granulocytes rose to a high level, then over a period of time fell to a lower level, although never as low as preoperative levels. Over a period of 3 years, the granulocytes remained at a considerably higher level than before the operation. The initial increase in red cell count and hemoglobin was contributed to, at least in part, by the blood transfusions given at the time of operation. It will be noted that a mild anemia persisted for most of the 3 year observation period, although there was some increase in red cell count and hemoglobin, especially during the last year. The patient received ferrous sulfate and liver extract for several months at a time without any

effect on the anemia. Fragility tests done on a few occasions since splenectomy showed a gradual increase in resistance of the erythrocytes to hypotonic saline. Seventy-eight weeks after operation, hemolysis began at 0.36 per cent saline and was complete at 0.18 per cent saline. Some target cells could be observed in the blood at this time. The blood platelets, which were reduced in number to as low as 49,000 before operation, rose to 602,000 a month later and have continued to be present in increased numbers since. Of interest in the hematologic course shown in Figure 3 is the fact that there was a gradual increase in

total white cell count and granulocyte count over a period of 3 years. Also of interest is the observation, again, of the inverse relationship of granulocytes and lymphocytes. From Figure 3 it will be noted that generally when granulocytes are increased, lymphocytes are decreased, and vice versa.

CASE 4 N J P, 2 year old, white female, was admitted to the pediatric service for the first time on September 15, 1944. At this time a history of tonic convulsions of 6 weeks' duration was elicited from the parents. Her past history revealed a normal full term birth. Nutrition had been consistently poor. At the age of 1½ years, she was treated for an anemia of undetermined type at another hospital.

Fig 4 Patient N J P Adrenalin test.

Physical examination revealed a pale, chronically ill child. Her weight was 7.5 kilograms. Her skin was pale and the subcutaneous tissue scant. The heart was questionably enlarged to the left and a systolic murmur at the apex was transmitted to the axillae. The spleen was palpable just beneath the costal margin, and the liver was palpable 3 centimeters below the costal margin.

Initial blood findings showed a hemoglobin of 5.5 grams per 100 milliliters, erythrocytes 1,200,000 per cubic millimeter, and leucocytes 2,000 per cubic millimeter. A differential count showed segmented neutrophils 28.0 per cent, lymphocytes 58.0 per cent, large mononuclears 10.0 per cent, and eosinophiles 4.0 per cent. A platelet count showed 50,000 thrombocytes per cubic millimeter, and reticulocyte counts were less than 2.0 per cent. Several blood transfusions were given during the hospital course. Sternal marrow aspiration showed a nucleated cell count of 38,300 per cubic millimeter, erythrocyte count 3,240,000 per cubic millimeter, and hemoglobin 10.4 grams per 100 milliliters. A differential marrow count showed neutrophils 18.6 per cent, eosinophiles 4.6 per cent, basophiles 0.6 per cent, unsegmented neutrophils 14.6 per cent, metamyelocytes 15.2 per cent, myelocytes 10.8 per cent, myeloblasts 4.4 per cent, lymphocytes 16.4 per cent, monocytes 0.8 per cent, normoblasts 10.6 per cent, erythroblasts 2.0 per cent, megaloblasts 0.8 per cent, plasma cells 0.6 per cent, and megakaryocytes 0. The granulocyte nucleated red cell ratio was 5.13-1.00. The marrow was considered essentially normal. Radiographic examination of the chest showed slight enlargement of the cardiac silhouette toward the left. An electrocardiogram was normal. At the time of discharge September 9, 1944, the hemoglo-

bin was 8.0 grams per 100 milliliters, erythrocytes 2,880,000 per cubic millimeter, and leucocytes 4,000 per cubic millimeter. A tentative diagnosis of primary splenic neutropenia was made.

The patient was readmitted on November 21, 1944, and again on May 2, 1945. The blood findings before and after operation are found in Table II. An epinephrine test is shown in Figure 4. On May 25, 1945, a splenectomy was performed. The spleen weighed 32 grams and measured 7.0 by 4.5 by 2.0 centimeters. Two accessory spleens were also removed. Microscopic examination of fixed sections showed no demonstrable phagocytosis, moderate follicular hyperplasia, and hemosiderin pigmentation. A final diagnosis of splenic panhematopenia was made.

The patient was readmitted on several occasions for follow-up studies and acute respiratory infections, as shown in Table II. On her last admission on September 3, 1946, the hemoglobin was 10.5 grams per 100 milliliters, erythrocytes 4,600,000 per cubic millimeter, and leucocytes 15,000 per cubic millimeter. A differential count showed segmented neutrophils 70 per cent, lymphocytes 25 per cent, monocytes 2 per cent, and eosinophiles 3 per cent. This patient subsequently died at another hospital on July 3, 1947. The cause of death is unknown.

CASE 5 L B, 50 years old, white, married female, was admitted to University Hospitals on July 12, 1945, with a complaint of pain in the joints of several

years' duration, which had become more acute during the past 3 months. The symptoms were thought to be the result of hypertrophic arthritis and she was admitted for study. Physical examination revealed a well nourished woman who did not appear acutely ill. There was slight sclerosis of the retinal arteries. The liver was palpable about 1 centimeter below the costal margin and the spleen was enlarged to 3 centimeters below the costal margin and was firm and nontender.

Blood findings are shown in Table III and Figure 5. It can be observed that there was a marked progressive drop in the total white blood cell count, especially of the neutrophils but also of the lymphocytes. Sternal marrow biopsy was done and imprint smears showed an active marrow. The differential count on Wright stained imprint smears was neutrophils 2.2 per cent, eosinophiles 4.2 per cent, basophiles 0.2 per cent, unsegmented neutrophils 12.4 per cent, metamyelocytes 11.0 per cent, myelocytes 21.6 per cent, myeloblasts 1.4 per cent, lymphocytes 10.6 per cent, monocytes 0.2 per cent, normoblasts 26.8 per cent, erythroblasts 7.0 per cent, megaloblasts 0, and plasma cells 2.4 per cent. The granulocyte nucleated red cell ratio was 1:57.

100. Fixed tissue sections of sternal marrow showed increased cellularity, with both erythrocytic and granulocytic cells participating. There appeared to be an increased number of eosinophiles present. The blood platelet count was 134,800, the bleeding time 2 minutes, and the clotting time 4 minutes with normal clot retraction. The prothrombin content (Quick's method) was 78 per cent of normal, the icterus index 3 units, the reticulocyte count 0.2 per cent, and the hematocrit 42 per cent. A diagnosis of primary splenic panhematopenia was made in which it was noted that the granulocytic series of white cells was particularly involved. Splenectomy was recommended. Preceding operation the temperature slowly rose until the day before operation it reached 40.2 degrees C.

Splenectomy was performed on July 19, 1945. At operation the spleen was found to be adherent to the diaphragm and was removed with some difficulty. During the operation considerable hemorrhage took place. The patient received 1000 milliliters of citrated whole blood during and immediately following the operation. The spleen weighed 575 grams and measured 20 by 12 by 5 centimeters. Supravital preparations (Janus green and neutral

cytes or neutrophils. These were not numerous and only a few could be found on prolonged search. There was an increased number of eosinophils present. Wright stained imprint of splenic tissue revealed an occasional very large phagocytic cell containing one or more neutrophils, erythrocytes, or nucleated red cell. These were not numerous and only 3 or 4 were found on prolonged search. Fixed tissue sections were not striking. No phagocytic cells could be seen. The germinal centers of the follicles appeared to have been "washed out" and contained fewer cells than normally seen. The final diagnosis was moderate hyperplasia of the spleen. The patient's postoperative convalescence was uncomplicated, and she was discharged on her 12th postoperative day. Hematologic findings, before and after operation, are recorded in Table V.

These patients presented the findings described by Doan (2) as occurring in primary splenic panhematopenia. Neutropenia, anemia, and thrombocytopenia occurred in all patients and varied from mild to severe. Splenomegaly was constantly present, but variable in degree. Purpura was observed, depending upon the degree of thrombocytopenia. Oral ulcerations were present in 1 patient and chronic ulcers on the legs of another patient, both of whom had severe, and presumably chronic, neutropenia. Mild jaundice occurred in only 1 of the 7 patients. The bone marrow was hyperplastic in all instances.

Examination of the spleen, in all instances, and an autopsy performed on 1 patient, did not reveal the presence of any other disease that might have accounted for the hematologic disturbance. There was no suggestion that leukemia or other diseases of the lymphoblastoma group were present. Findings characteristic of Banti's disease, Gaucher's disease, or Still's disease were not present. The histologic picture was not characteristic or specific, and generally no more than mild follicular hyperplasia could be demonstrated.

These patients also demonstrated certain characteristics which were somewhat unexpected. In spite of moderate or severe anemia, reticulocytosis was absent, except in 1 patient, E. D. Occurrence of reticulocytosis after splenectomy would tend to have been obscured, if present, by blood transfusions given at the time of operation.

The absence of visible jaundice, little or no elevation of the icterus index, and no increase of urinary urobilinogen were also notable

Fig 6 Patient A F Adrenalin test

With the exception of 1 patient, E. D., who also demonstrated reticulocytosis, the usual evidence of hemolysis was absent even in patients with severe anemia. Since fecal urobilinogen studies were not made on these patients, it cannot be said that conclusive proof against increased production of bile pigments has been offered. It is conceivable that even with excessive production of bile pigment due to rapid breakdown of erythrocytes, the liver was able always to clear the blood stream and prevent jaundice. In such a case, it must be presumed that the increased amount of urobilinogen was excreted entirely in the feces and not at all in the urine. That such a condition existed in all these patients seems unlikely, even though possible.

Because of these findings, it seems obvious that the anemia in these patients was not clearly hemolytic in origin and is not comparable to congenital hemolytic anemia. The most outstanding difference between the anemia of congenital hemolytic anemia and that of primary splenic panhematopenia, however, is the constant presence of spherocytosis in

the former and its constant absence in the latter disease. The usual patient with congenital hemolytic anemia exhibits leucocytosis and thrombocytosis at the time of crisis, unlike the patients in this series. Reticulocytosis, jaundice, and an increase in urinary urobilinogen are likewise common, if not constant, findings in congenital hemolytic anemia.

Idiopathic thrombocytopenic purpura also differs in certain characteristics from primary splenic panhematopenia. Splenomegaly is notably absent. There is no alteration in the erythrocytes unless hemorrhage has occurred. A leucopenia, but not specifically neutropenia, exists in some cases, although leucocytosis may be present if hemorrhage has occurred. Even so, it might be conceivable that idiopathic thrombocytopenic purpura could represent an instance of primary splenic panhematopenia in which the destructive action of the spleen was selective for platelets alone and in which enlargement of the spleen does not occur. In idiopathic thrombocytopenic purpura, however, specific changes are seen in the megakaryocytes which were not seen in any of these patients and have not been reported by others.

Failure to demonstrate excessive phagocytosis in the spleens of these patients affords a careful study of supravital, Wright stained and fixed tissue preparations makes it doubtful that phagocytosis is the mechanism responsible for the production of primary splenic panhematopenia. Other authors (6) have likewise commented on their inability to demonstrate phagocytosis. Moore and Bierbaum were able to demonstrate it in 1 of 3 cases.

A tendency for a delayed leucocyte response in certain of these patients, especially M. and H. H., with a slow return toward normal over a period of many months was also noted. If excessive phagocytosis occurring solely in the spleen, was responsible for the occurrence of the hematologic disorder, it would be reasonable to expect that splenectomy would produce an immediate, persistent, and complete return of the hematologic picture to normal. Indeed, if the spleen is the sole organ concerned in the production of the disease whatever the mechanism, such an immediate complete response might be expected. The abrupt return to normal in patients with congenital hemolytic anemia and in some cases of idiopathic thrombocytopenic purpura for

lowing splenectomy is well known, although it is not uncommon to observe a gradual, rather than abrupt, increase in platelets following splenectomy in cases of thrombocytopenic purpura

In our experience, the epinephrine test has not been of aid in the diagnosis or interpretation of the mechanism of this syndrome. The rise in leucocyte count following the administration of epinephrine is the result of the appearance of increased numbers of lymphocytes in the peripheral blood, with little change in the number of polymorphonuclear neutrophils. The change in erythrocyte, hemoglobin, and platelet levels (not recorded in the charts) has been too small to be subject to interpretation, and similar changes have been observed in normal individuals and even in individuals who have undergone splenectomy. These findings, coupled with failure to find increased numbers of myeloid cells in the spleen, either free or phagocytized, make it more doubtful that sequestration and phagocytosis of cells in the spleen can be considered the primary mechanism of the syndrome.

The role of the spleen in this disease is, therefore, not clearly defined at this time, especially if patients with this syndrome continue to show absence of excessive phagocytosis. An alternative explanation, which seems to us to be better correlated with the findings, is that the spleen has a regulatory effect on bone marrow as proposed by Dameshek in idiopathic thrombocytopenic purpura. The anemia, not clearly hemolytic, may be the result of failure of proper discharge of erythrocytes from the marrow. The presence of neutropenia and thrombocytopenia could be explained, likewise, on the basis of suppression of discharge of these elements from the marrow. Direct proof, however, of such a mechanism is lacking at this time. Ungar (8) has demonstrated an endocrine-like relationship between the pituitary and the spleen in protein metabolism and claims to have isolated from the spleen a pure crystalline material which is responsible for this effect. Singer, Miller, and Dameshek likewise have claimed to demonstrate that lysolecithin, produced by the spleen, has a regulatory effect on erythro-

cytes. Further study is necessary to determine whether the hematologic findings in primary splenic panhematopenia might be the result of a similar regulatory mechanism.

SUMMARY

1 Seven patients are described with the clinical and laboratory findings characteristic of primary splenic panhematopenia. After splenectomy 1 patient died, the 6 others were markedly improved.

2 Jaundice, urobilinogenuria and reticulocytosis were not as evident as would have been expected if the anemia was of a simple hemolytic nature.

3 Following splenectomy, hematologic improvement tended to be gradual and prolonged rather than immediate and complete.

4 Excessive phagocytosis of myeloid elements could not be demonstrated in the spleens of these 7 patients.

5 Examination of the spleens in all instances, and one autopsy, did not reveal the presence of any known disease. The spleens were enlarged and generally showed varying degrees of follicular hyperplasia. In only 1 patient was there an increase of myeloid elements in the splenic pulp.

6 It is questionable that congenital hemolytic anemia and idiopathic thrombocytopenic purpura are members of this syndrome.

7 Since excessive phagocytosis could not be demonstrated in these patients, it is suggested that some regulatory action of the spleen on bone marrow may be the mechanism responsible for the hematologic disorder.

THE INDICATIONS FOR HYSTERECTOMY

THE word hysterectomy is derived from the Greek,—*Hyster*a, uterus and *Ectome*, excision. Therefore, it means excision of the uterus. This term is applied to the uterus alone and does not include the tubes and ovaries. If the oviducts and ovaries are also removed, the term hysterectomy must be followed by unilateral—right or left, bilateral salpingo-oophorectomy, or hysterosalpingo-oophorectomy. Hysterectomy may be total or subtotal, and may be performed for either malignant or benign disease of the uterus and adnexa. Synonyms for total hysterectomy are complete hysterectomy and panhysterectomy, while those for subtotal hysterectomy are partial, supravaginal, supracervical and fundic hysterectomy. The extirpation of the uterus may be performed through the abdomen—abdominal hysterectomy, or through the vagina—vaginal hysterectomy.

Carcinoma of the uterus, cervix or corpus, sarcoma of the uterus and chorionepithelioma are the malignant diseases for which hysterectomy is generally indicated. In the presence of malignant disease the total operation is always performed and should be accompanied by the ablation of the adnexa, because of the frequent metastases to these structures. While the majority of carcinomas of the cervix uteri are treated by radium and high voltage x-ray, the radical abdominal panhysterectomy, commonly referred to as the Wertheim operation, is reserved, by some surgeons, for malignant disease of the cervix uteri in certain group I and group II cases, League of Nations classification. This intervention consists of the suppression of the entire uterus, the tubes, the ovaries, the pelvic connective tissue after dissection of the ureters, the vagina almost entirely, and the obturator and iliac glands. The radical vaginal hysterectomy, proposed by Schauta for the same indication, namely malignant disease of the cervix, does not afford as satisfactory exposure as does the abdominal intervention and has, therefore, never acquired the popularity of the latter among the majority of pelvic surgeons.

In the treatment of malignant disease of the corpus uteri, such as carcinoma, adenocanthoma and chorionepithelioma, radium or high voltage x-ray should be applied, and, in the course of five to six weeks this should be followed by a panhysterectomy and bilateral salpingo-oophorectomy. Exposure to radium or x-ray so modifies or eliminates the carcinomatous cells that their implantation elsewhere at the time of operation is greatly reduced or totally prevented. In sarcoma of the uterus radium or x-ray are not employed because

these agents have very little effect on this type of tumor, but the total hysterectomy with the excision of the adnexa should be performed as soon as the diagnosis is established. Malignant neoplastic disease of the oviducts and ovaries demands the total removal of the uterus with the pathological adnexa.

The indications for hysterectomy for benign disease are fibromyoma, the most common indication, uterine prolapse when it is accompanied by uterine bleeding or when the uterus is pathological,—vaginal hysterectomy, inversion of the uterus, when gangrene and infection have set in, myometrial hypertrophy associated with hyperplasia of the endometrium and hemorrhage, cesarean hysterectomy, in the presence of fibromyomas, infection, and hemorrhage, pelvic inflammatory disease, specific, tuberculous and puerperal, when the involvement of these structures is marked, and in endometriosis, interna and externa, when the pathology is extensive and cannot be treated by conservative measures. When hysterectomy is performed for benign uterine disease, the adnexa are removed if pathological, and conserved, as a rule, if normal.

In myometrial hypertrophy with endometrial hyperplasia and hemorrhage, and in certain intramural fibromyomas, which in size are not larger than a three month gestation, hysterectomy enters into competition with irradiation by means of radium or high voltage x-ray. Irradiation will control the bleeding, and the small fibromyomas will regress after this form of therapy, but the organs remaining *in situ* may be the seat of carcinoma of the uterus or ovaries a number of years later—fifteen years from my observation. Irradiation in the treatment of these conditions is a valuable procedure in the poor surgical risk, in one whose physical condition precludes the performance of an operation so extensive as a hysterectomy, but, when there is no con-

traindication, hysterectomy, with or without the ablation of the adnexa, as the case may be, shows a certain superiority over irradiation since it insures the patient against future disorders of these organs.

The question of total versus subtotal hysterectomy is still unsettled. The literature of the past two decades definitely shows that an increasing number of surgeons are performing the complete operation as routine, and reserving the subtotal operation for special conditions, this being a complete reversal of the opinions of a half a century ago. The advantages of the total over the subtotal hysterectomy are absolute prophylaxis against carcinoma of the cervical stump, protection against benign tumors of the cervix, such as cervical fibromyomas, the avoidance of the so called bleeding cervix from benign causes, and the prevention of an annoying leucorrhea which frequently originates in the cervix after the suppression of the uterine corpus. The disadvantages are said to be the operation is more difficult of execution, the operative mortality and morbidity are higher, the danger of injury to the bladder and ureters is greater, and finally the vagina is shortened. However, it has been proved by statistics, that in the hands of surgeons well trained in the performance of this operation, the mortality and morbidity of panhysterectomy need not be greater than that of subtotal hysterectomy, and that also, in the hands of surgeons so trained, injuries to the bladder and ureters are uncommon. The shortening of the vagina need be but very slight if the vagina is cut close to the cervix, and after its closure, it is well supported by the fascia endopelvina, aided by the round and uterosacral ligaments. An increasingly large number of operators are of the opinion that the advantages overbalance the disadvantages of the complete operation.

LOUIS E. PHANEUF

VAGINAL HYSTERECTOMY

THE removal of the uterus by the vaginal route is an operation of considerable age, in spite of what one might judge from the discussions at gynecological assemblies. Probably no operation has had as many "ups and downs" as has vaginal hysterectomy. Preceding the introduction of aseptic technique, the mortality following the abdominal removal of pelvic tumors was so high that it was performed only under the greatest urgency. At a meeting of the American Gynecological Society in 1880 a series of 119 abdominal hysterectomies for fibroids was reported with a mortality of 64 per cent. At the 1886 meeting, it was stated that abdominal hysterectomy was so highly dangerous that it was rarely warranted.

In 1876 Czerny revived the vaginal hysterectomy technique of Souter of Constance, and it rapidly came into vogue both in Europe and in this country, and abdominal hysterectomy was performed but rarely. Large series of vaginal hysterectomies were reported from all medical centers. Great dexterity in technique was developed so that even large fibroids were removed by morcellation, and both ovarian and uterine tumors, even complicated by inflammation of the appendages, were removed vaginally with far greater safety than by the abdominal route. In 1884 Mundé stated that the day following a vaginal hysterectomy for cancer lasting two hours, the patient usually appeared no worse than if she had been delivered of child.

When at the end of the last century aseptic surgery became perfected, the abdomen was entered with relative safety. Gynecologists largely deserted the vaginal attack on pelvic disease and entered the abdomen, so that in addition to doing the indicated surgery, they might also remove the chronic appendix. They

learned about cecum mobile, Jackson's membrane, Lane's kink, and devised procedures for their attention, and they shortened the mesentery of the colon, if it appeared longer than pleased them. Meddling minds found much to do. Follicular cysts were punctured or cauterized, and if no cysts were present, the ovaries were resected if the patient menstruated too much or too little. In most clinics vaginal hysterectomy was abandoned entirely and a generation of gynecologists grew up totally unacquainted with the vaginal approach to pelvic disease. As well known a gynecologist as Floyd Keene of Philadelphia, the head of a large and important teaching unit, lived and died without ever performing a single vaginal hysterectomy nor did he ever see his former chief, John Clark, do one. In only a few centers in this country was the operation performed, though it still survived in the German clinics.

American gynecologists, spending their residencies in Germany, were impressed with the easy recoveries of the patients operated upon vaginally as compared to the convalescences of patients operated upon abdominally, and upon their return reintroduced vaginal surgery to American gynecology. The mortality after vaginal hysterectomy, under comparable conditions, is much lower than after abdominal hysterectomy. A shorter period of anesthesia is required. Shock is extremely rare. Vomiting and gas pains are much less severe. Bowel obstruction is very unusual. Paralytic ileus hardly ever occurs. Bleeding from the vaginal hysterectomy itself is usually less than from an abdominal incision alone. The patient is not so sick and the hospital stay much shorter. The period of convalescence is not so protracted and the patient may resume her usual duties in a much shorter time. Postoperative hernia and eventration are, of course, unknown.

Now that we know that chronic appendicitis is largely mythical and the procedures accessory to an abdominal hysterectomy are frequently harmful and meddlesome, it is high time that vaginal hysterectomy assumes its rightful place in gynecology. It is interesting to note how those who persist in perfecting themselves in the technique of vaginal hysterectomy gradually disregard more and more of the contraindications so insistently laid down by those with little or no familiarity with the operation. When the operator's technique is finally perfected, he finds it easier to remove the uterus through a nulliparous or virginal pelvis, if the vaginal vault is ordinarily capacious and is not constricted or infantile, than if relaxation is considerable.

Under certain conditions, a vaginal hysterectomy is strictly indicated and no other procedure is even a passable substitute. A young woman, for example, under thirty-five has an uncontrollable menorrhagia. She has had several curettements with only temporary or no relief. All styptics have failed and all the directions of the endocrine wizards have been conscientiously but unsuccessfully followed. The patient is extremely obese or is otherwise a poor operative risk, and an abdominal hysterectomy would be extremely hazardous. Under these conditions radium is ordinarily administered. The patient's menorrhagia will be relieved, but the annoyances of

the menopause will be added to her already long list of complaints. Estrogens cannot be safely given and the patient may later have the delayed effects of the radium. Under these circumstances a vaginal hysterectomy might very safely be performed, I have never yet substituted radium therapy in a patient in whom vaginal hysterectomy is indicated. However, if one is to confine the use of vaginal hysterectomy to only such patients as present absolute indications, he will not have the necessary dexterity to operate upon such patients when the necessity arises. The Kjelland forceps is frequently a fetal life saver. If the obstetrician does not familiarize himself with its use as mid and low forceps, where it is not necessary, he will not know one blade from the other when great familiarity is necessary for the occasional case in which it is strictly indicated.

Is a gynecologist competent when he gives radium to a patient who really needs a vaginal hysterectomy because he is not able to do the particular operation that is indicated? Is a man a specialist, in a field as restricted as is gynecology, unless he can do the special operations applicable to that province? Particularly, would one expect that, when a surgeon is certified by an examining board which limits the area of his activities, he would be able to perform every operation peculiar to his restricted sphere?

I VESALIUS' CENTURY

THE sixteenth century was marked by exuberant achievements in all fields of human endeavor. This was the century of William Shakespeare (Fig 1), Francois Rabelais (Fig 2), Sir Thomas More (Fig 3), Francis Bacon (Fig 4), Galileo Galilei (Fig 5), and of Girolamo Fracastoro, Leonardo da Vinci (Fig 6) and Ambroise Paré (Fig 7), of John Calvin (Fig 8) and Martin Luther (Fig 9), of Miguel de Cervantes (Fig 10), Sir Francis Drake (Fig 11) and Sir Walter Raleigh, of Henry VIII of England (Fig 12) and Henry II of France. It was the age of Giovanni Marinello, Carlo Ruini, Niccolo Machiavelli, Hans Holbein, Guilelmus Rondeletius, Richard Hakluyt, Nicolas Monardes, Tiziano Vecellio, Ulysses Aldrovandi, Benvenuto Cellini, and Albrecht Durer.

To Shakespeare we owe the robust humor of Falstaff and the ethereal plaint of Ophelia, the macabre intrigue of Macbeth and the whimsy and prank of Puck and Bottom, the reverie of Juliet and the stratagem of Caesar, the gemmy beauty of Cleopatra and the sinister hideousness of three witches. Comparably, Francois Rabelais excelled

as a story teller, as did Sir Thomas More and Francis Bacon in the fields of statecraft and philosophy. Galileo Galilei found a magnetic core for the Earth, and Leonardo da Vinci and Tiziano Vecellio painted masterpieces, to fasten wings of glorious hope on mankind's concepts of heavenly aspiration. Ambroise Paré, surgeon to four successive kings of France, not only spread new knowledge of surgery, but also wrote expansively of his journeys with the armies of the French kings. Girolamo Fracastoro, in his treatise of contagion, set forth a prevision of infection by micro-organisms. Martin Luther and John Calvin liberated religion from hierarchic domination. While the churchmen brought clerical balm to the soul, Giovanni Marinello, with mundane practicality, laid the groundwork for epidermal rehabilitation in his volume on cosmetics, perfume, and hair-dyes. Aware of the importance of cavalry in the game of war, Carlo Ruini prepared an illustrated treatise on the anatomy of the horse. Niccolo Machiavelli codified military and diplomatic methods and practices for the guidance of aggressive monarchs. Keeping pace with the expansion of ambitious nations, Johann Huttichius compiled his collection of voyages and discoveries in the New World, and Richard Hakluyt published his account of the principal navigations of the English nation. In the field of zoology Guilelmus Rondeletius wrote on the subject of fishes, and in that of botany Nicolas Monardes described therapeutically the "rare and singular virtues" of the herbs, trees, oils and stones brought from America. The biological sphere was further widened by the contents of folios, from the hand of Ulysses Aldrovandi, on various aspects of natural history, including the occurrence of human monsters. Benvenuto Cellini worked exquisitely with precious stones and metals, while Albrecht Dürer excelled in the handling of wood engravings.

The First Brödel Memorial Lecture read at the Chicago (September 1948) meeting of the Association of Medical Illustrators. More than a half century ago (1894) Max Brödel came to Baltimore, from Leipzig at the behest of Dr. Franklin P. Mall for an immediate association with Dr. Howard A. Kelly and later with Drs. Thomas S. Cullen and William S. Halsted and their eminent colleagues.

Mr. Brödel was an enemy of plagiarism—against which larcenous practice Vesalius had inveighed and the malignant abuses of which he had suffered deeply. Aware of the fact that sometimes larceny is a way of taking what one cannot create and recognizing that medical pictures were being done by artists untrained and therefore inescapably dependent upon predecessors, Mr. Brödel established the first department of art as applied to medicine.

For biographical material dealing with the life and achievements of Mr. Brödel the reader is referred to the following articles: *J Am M Ass* vol 110 no 11 March 12 1938 pp 817-818 p 823; *ibid* vol 117 vol 9 August 30 1941 pp 668-67; *Bull Med Libr Ass* vol 33 no 1 Jan 1945 pp 6-9.

of productive skill. The artists in particular found outlet for their fervor in preparation of magnificent illustrations for those of their contemporaries who labored in the biological sciences. Briefly, there were playwrights, play-actors and essayists, inquisitive ecclesiastics and searching scientists, conquerors and chroniclers, monarchs and monastics, artists and artisans, political planners and pietistic pieceworkers.

It would have been strange, indeed, had this surge of creative force failed to inspire some inquisitive and sagacious scholar to unriddle the mystery of human fabric. Men were now thinking with anthropocentric bias, and the ultimate product of Nature's perfect contriving could not be long neglected. Appropriately, the study of

man was lifted to a station of suitable loftiness in the folio treatise of Andreas Vesalius.

2 PRIMITIVE ANATOMIC FIGURES¹

Only when the early books, antecedent to, or contemporaneous with, the appearance of the

¹Almost all of the anatomic illustrations reproduced herein were photographed from the original works in the Archibald Church Library of Northwestern University Medical School. However for material from manuscripts and incunabula the writer was dependent chiefly upon the following sources: *History and Bibliography of Anatomic Illustration* Ludwig Choulard (transl. and ed. Mortimer Frank) Chicago University of Chicago Press 1920. *Atlas of the History of Medicine Anatomy*, J. G. De Lint. New York. Paul B. Hoeber, 1926.

The pictures of personages (Figs. 1 to 12) were copied from the following source-books: *Portraits of Illustrious Personages of Great Britain* London Printing and Publishing Co. *Imperial Dictionary of Universal Biography* Glasgow William Mackenzie.

Tabulae are examined does the excellence of the Vesalian figures become impressive. If morphological Vesalian torchbearers would be referred to the Nuremberg plate which played

skeletal

the bones articulated and named in bannered labels (Fig. 13) or to some equally primitive representation of man's supportive framework. Details would later have been supplied by the

Fig 19

figures of Charles Estienne (Fig 14), whose lengthy folio, *De Dissectione Partium Corporis Humani, Libri Tres*, was published in 1545. For the dissector, recourse could have been made to the work of Guido de Vigevano, which recorded successive anatomic levels in serial lamination, pictured a method of anatomizing the cadaver (Fig 15), and made such fabulous additions to human anatomy as the seven-celled uterus. Other writers stressed the configuration and topography of the thoracic and abdominal organs, and the disposition of the ventricular spaces within the brain. For example, in the visceral figure from Peyligk's *Philosophia Naturalis* (1499), the morphology of the brain and of the thoracic and abdominal organs, is handled in stylized fashion (Fig 16). The cerebral ventricles are superimposed upon a calvarium. Pulmonary and coronary anatomy is diagrammatized, the lungs and heart lie cranial to an oblique line which repre-

Fig 20

Figs 19 and 20 Illustrations from works by Vesalius' contemporaries

Fig 19 Plate from the *Tabulae Anatomicae* of Bartolomeo Eustachio (Venice, 1749)

Fig 20 Sketches by Leonardo da Vinci

sents the diaphragm. The gourd-shaped stomach is clasped on one side by a flattened spleen, on the other by a crenate liver, an abbreviated intestine is tied in a lover's knot. Equally rude is the visceral figure from Hundt's *Antropologium*, published in 1501 (Fig 18), and the comparable illustration from Reisch's *Margarita Philosophica*, which appeared in 1503 (Fig 17). In Reisch's illustration (Fig 17), as in Peyligk's (Fig 16), the various labels are placed upon or near the structures. In the picture from Reisch's work (Fig 17), the liver (labelled *epar*), the stomach, and the spleen are of more natural form, yet, curiously (perhaps through the delineator's error), the small intestine, shown uncoiled but neatly piled, opens into the urinary bladder (*vesica*). The reader views the body from the front, not as in Reisch's picture, wherein the head is revolved to face the specimen's back (Fig 16). In the illustration from Hundt's *Antropologium*, the heart is merely superimposed upon the lungs (Fig 18), a relatively enormous liver, with crenate border, clasps a gourd-shaped stomach, the latter is connected with the spleen by a "duct" which is quite as

venty-seven muscle figures published in 1542, as later destroyed by the author himself on the conviction that his work would be inferior to that of Vesalius. Bartolomeo Eustachio, whose plates, long mislaid, were not published until 1714 in the *Tabulae Anatomicae* (Fig. 19) Leonardo da Vinci whose sketches in Tusimile alone stand in evidence of his genius (Fig. 20) and Andreas Vesalius, author of the *De Humani Corporis Fabrica* (Fig. 21) the most influential volume ever composed on the gross structure of the human

body. Vesalius' works in revised form were still copied two hundred years after the publication of his monumental folio.

4. VESALIUS: LIFE AND WORK

In the true sense Vesalius' rise and his brilliant showering of knowledge upon lesser men were meteoric in intrinsic character and in historic effect. His own life was so brief as to be a transient luminosity, but when regarded as the source of lesser luminaries whose claim to fame is

Fig 34

Fig 35

Figs 30 to 35 Large initial letters, *Fabrica*, 1555 edition Introducing the dedication and the several books

pended upon his genius, then, indeed, does he appear as the center of a constellation (portrait, frontispiece)

Vesalius was born in Brussels on the last day of the year 1514. At an early age he matriculated in the nearby University of Louvain. For his graduate thesis he composed a paraphrase of the popular medieval compendium of medicine, the ninth book of Rhazes, to correlate the Arabic writings with those of Galen. In this endeavor he took special pleasure, since a commentary on the books of Rhazes had been prepared by his grandfather. Vesalius' father was one-time apothecary both to the Emperor Maximilian, and to his son, the Archduke Charles, and to the latter when he became Emperor Charles V of Austria.

With an inquisitiveness nurtured by careful study, Vesalius, at the age of eighteen, travelled to Paris to obtain a medical education. At the outbreak of the third Franco-German war, in 1536, Vesalius returned to the University of Louvain. Shortly after the publication of the *Paraphrasis*, Vesalius journeyed to Italy, selecting for residence the prosperous and enlightened Venice. There he practiced minor surgery and conducted public demonstrations. While there, he met Jan Stephan van Calcar, whom he subsequently selected to illustrate his magnificent works. During his stay in Venice, Vesalius prepared his own edition of Guenther's *Institutiones anatomicae* in 1538, others followed, to 1613. Of all the many commentaries on Galen's works printed during the late Renaissance, few proved

more popular than Johann Guenther's manual of four books, which had been specifically prepared for medical students. Vesalius also edited the *Opera Omnia* of Galen, with the aid of other scholars, he converted the original Greek text into readable Latin. Fourteen editions, published between 1541 and 1551, contain some of the Vesalian renderings. Such progress did Vesalius make after reaching Venice that before the year was out, on the 6th of December 1537, just before his twenty-third birthday, he received the celebrated appointment from the Venetian Senate, enabling him to teach anatomy at the University of Padua.

Before his transfer to Padua, Vesalius had, doubtless in collaboration with Calcar, begun work on six anatomical plates (*Tabulae Sex*), which were printed in Venice in April of the following year (1538). They depict the portal system, the liver, kidneys and caval veins, the heart with the aorta and its branches, the skeleton in three views (front, right profile, and from behind).

The printing of these "anatomical fugitive sheets" created a great stir, a set forwarded by Andreas to his father at Court was presented to the Emperor, who praised them highly. They were plagiarized and counterfeited by Jobst de Necke, printer and publisher (1539), by Aegidius Macrolis (1539), by Walter Ryff (1541), who increased the number of figures to ten, by Johann Dryander (or Eichmann), who copied the figures in his *Anatomia Capitis Humani* (1536). Additionally, in figures of the *De Dissectione* of Charles Estienne (1545), the influence of the *Fabrica* is

Fig 36

clearly apparent in many of the small insets, in the *De Chirurgica Institutione* of Johann Tagault (a popular book, which passed through twenty-two editions between 1543 and 1645), the Calcar figures were abominably copied

These anatomical plates of Vesalius were designed particularly to benefit those who attended his dissections, just as the exhibitor today distributes mimeographed sheets or reprints among

visitors to his booth at a state or national medical meeting

The popularity of even such a modest set of carefully prepared figures must have encouraged Vesalius to undertake the great task of writing a complete work on human anatomy. Possessed of the enthusiasm of a zealot, Vesalius completed the *Fabrica* after three years of strenuous labor. The drawings were done by Calcar. In the same month

Vesalius finished the *Epitome* of his great work, the *Fabrica*. The plates of the *Epitome* were issued unbound, like the *Tabulae*, they were ephemeral, and hence perfect copies are excessively rare. The *Epitome* contains five plates of the musculature and figures of a nude man and woman.

Only eighteen years after the appearance of the *magnum opus*, at the age of fifty, Vesalius was drowned in a shipwreck off the island of Zante on

his return from the Holy Land, where, according to rumor, he had been sent on a journey of expiation.

5 THE FABRICA OF ANDREAS VESALIUS

a EDITIONS OF THE FABRICA

The original edition of the *Fabrica* appeared in 1543, from the press of Oporinus, in Basil. The

work extends over six hundred sixty-three folio pages, it is composed of seven books, and contains twenty-two full-page woodcuts and numerous smaller figures in the text

The frontispiece shows Vesalius beginning to anatomize a female cadaver (cf Fig 70, from the second edition) Because methods of preservation were then unknown, removal of the organs, first

to putrify, was carried out quickly This dissection introduced the three day demonstration In order to record his conviction that the study of anatomy should begin with the osseous framework of the body, Vesalius has the skeleton placed in a position of central importance

Following the appearance of an unillustrated pocket edition (in Lyon, 1552), the second folio

Figs 70 to 75 Title pages of two editions of Vesalius' *Fabrica* (Figs 70, 71) and of anatomical treatises related thereto (Figs 72 to 75)

edition, of eight hundred twenty-four pages, was published in Basil in 1555. This edition is said to have been lavishly prepared for, the paper was to be heavier and the type larger, the latter change necessitated the recutting of all the small initial letters so that they would equal the height of seven lines of the new type. A new block was cut for the frontispiece (Fig 70), and the head of Vesalius was more effectively portrayed. The skeleton now carries a scythe, for concomitant exhibit of comparative anatomical features, lackeys lead a goat, as well as a dog, into the amphitheatre.

A posthumous edition of five hundred ten pages was published in Venice (1568), another of equal length followed, during the first decade of the seventeenth century (Venice, 1604).

b CONTENTS AND TABULAE, 1555 EDITION

The edition of 1555 is regarded by many collectors as the preferred volume in this distinguished series. Each of the books, or sections, is ampler than the corresponding parts of the editio prin-

Fig 70, left *Fabrica*, 1555 edition
Fig 71 *Opera Omnia* of Hermann Boerhaave and Bernhard Siegfried Albinus (1725)

ceps. It will serve as the chief basis of the present account.

The first book, devoted to the anatomy of the bones and cartilages, covers two hundred eight folio pages. Types of cranium are figured, and the skull is shown in all effective views. The presentation of vertebral anatomy would be adequate for present-day, critical use. All flat and long bones are illustrated from every advantageous angle. The book closes with three full-page skeletal figures and as many pages of legend (Fig 21).

The second book, dealing with the morphology of the muscles and ligaments, covers two hundred twenty-seven pages. Its text is supported by a superb set of illustrations, beginning with the musculature of the anterior surface of the body (Fig 22). Like any of the others, these illustrations are explained by didactically clear legends, each approximately two and one-half pages in length. Several of them depict flayed figures, ingeniously displaying muscles in successive laminae.

Fig 72 *Anatomia del Corpo Humano* of Valverde di Hamusco (1560)

The third book, concerned with the anatomy of veins and arteries, covers seventy pages. The figure of the portal system is particularly graphic in its display of venous channels which converge upon the liver. The treatment of the systemic veins is equally fine, the figure showing all regular segmental and axial veins together with the dural venous sinuses (Fig 23).

In the fourth book the cranial nerves are described and figured, this section covers forty-seven pages. Particularly striking are the figures of the recurrent laryngeal nerves and the full course of the vagus, and of all the larger peripheral nerves of the body (Fig 24). The last-named figure shows, with unusual effectiveness, the simple segmental scheme of the thoracic nerves, the cervical and the lumbosacral concentrations, and the lengthening which nerves must undergo to reach the upper and lower extremities.

The fifth book covers one hundred forty-three pages and deals with the "organs of nutrition," a category which includes the abdominal part of the alimentary tract, the urinary and reproductive organs, and the spleen. The figures are not only detailed and topographically excellent, but also

Fig 73 *Anatomia Reformata* of Thomas Bartholin (1655)

attractively statuesque (cf Fig 87), they possess the artistic character, despite partial evisceration, of the Belvedere torso by Apollonius and of the Farnese Hercules of Glycon. Stratification is accounted for from omentum to posterior parietes. In the anatomy of the kidneys, even the capsular vessels are illustrated.

The sixth book covers fifty-seven pages and describes the heart and "servant" organs (lungs, trachea), and the pleural and pericardial investments (Fig 25). Of paramount importance in functional theory was the nature of the septum between the cardiac ventricles. Long regarded as foraminous, for the passage of the elaborated spiritus, descriptions of this wall had been warped to fit an ancient concept of "vascular" movement. Against the influence of centuries of medical, philosophical, and ecclesiastical writing, Vesalius described the partition as he found it, that is, as an impervious interventricular wall. In the 1543 edition of the *Fabrica*, Vesalius repeated the Galenic notion that openings exist in the septum

of the heart. In the second 1555 edition, Vesalius corrects the statement, saying that the septum of the heart is as dense and impermeable as the outer walls.

The seventh book extends over seventy pages, describing the brain and each meninx (Fig 26). Cerebral divisions, ventricular spaces with contained choroidal plexuses, dural venous sinuses, the eminences on the dorsum of the brain stem, and the basal ganglia are shown clearly in admirable illustrations.

C INITIAL LETTERS, 1555 EDITION

Because the anatomical figures of the *Fabrica* are so utterly superior to illustrations published prior to 1543, the less obvious beauty of the decorative initial letters in the Vesalian masterpiece has captured the attention of relatively few English writers. The woodcut figures deserve appreciative comment, in introduction to which tribute their medieval lineage requires brief discussion.

Fig 75 The same work.

In Germany, during the fifteenth century, the size, form, and style of the printed book was evolved. It was a direct descendant of the ancient manuscript. At the outset particularly it retained some of the ornamental character of the manuscript, wherein numerous border embellishments, supplementing the copied script, were employed either as pure ornaments or as scenes illustrative of the text (Fig 27). Some were page-size, others were initial letters with pictorial background or interlaced Arabesque elements. Their history now requires a review.

In many of the books published during the sixteenth and seventeenth centuries the printers employed ornamental devices to add an attractiveness to their products which letterpress, unembellished, would fail to contribute. These initial letters, head-pieces, tail-pieces, and borders again show the intellectual vigor of a renaissance world.

The earliest initials produced by mechanical means, in the printed book, appeared as early as

1457 During the sixteenth century, woodcut initial letters were made in profusion. By the close of the seventeenth, their employment was a rarity.

As might be expected, subjects for these various ornaments were not selected without reason, most frequently their motivation was basically religious.

Perpetuating the tradition of the early manuscript, the monumental folios of the *Fabrica* were decorated with many historical woodcut initials. These ornamental capitals depict cherubic youngsters, usually naked, who, with intent demeanor and solemn visage, act out the parts of curator, laboratory aide, male nurse, orderly, physician and surgeon. The letters B, G, J, K, U, W, X, Y, and Z are wanting in the series. Certain of these, of course, would not appear in Latin writing. The initials I, L, O, Q, T, and V are reproduced with two different backgrounds. In these six instances one of the pair of letters is of the large type (Figs 30 to 35), all of the others are smaller, and of

Fig 77 *Catoptrum Microcosmicum* of Johann Remmelin (1619)

matching size.¹ The large blocks, 73 millimeters square, are placed at the beginning of the dedication and introduce the text of each of the seven books (Fig 28). The letters of intermediate size, 39 by 41 millimeters, head the chapters (Fig 29). Altogether, the initial letters appear a total of one hundred ninety-two times.² The

¹For the dedication and for the seven books of the *Fabrica* five different historiated initials are used while three are repeated. The V (Fig 35) introduces the dedication. Continuing in the succession the initial O (Fig 37) introduces liber primus (p. 1) and T (Fig 34) serves in like capacity for liber secundus (p. 209). The initial O is repeated for liber tertius (p. 456) and T for liber quartus (p. 507). Liber quintus is introduced by title and by a main anatomical illustration of the peritoneum; the text is introduced by a repeated V (p. 589). Liber sextus is similarly arranged: the book opens with heading and illustration of the thoracic viscera while the initial letter Q follows (p. 708)—repeated from early use in the body of the text of liber secundus (p. 255). In liber septimus on similar plan the book is introduced by heading and illustrations of cranial anatomy; the text following seventeen pages later (p. 772) carrying the initial letter I (Fig 30).

²In the 1555 edition the individual initial letters are employed the following number of times: A (Fig 36) 10 times C (Fig 37) 15 D (Fig 38) 10 E (Fig 39) 8 F (Fig 40) 5 H (Fig 41) 9 I (Fig 42) 18 J (Fig 30) 1 L (Fig 43) 10 L (Fig 31) 1 M (Fig 44) 9 N (Fig 45) 3 O (Fig 46) 7 O (Fig 32) 2 P (Fig 47) 17 Q (Fig 33) 2 Q (Fig 48) 20 R (Fig 49) 5 S (Fig 50) 12 T (Fig 34) 12 T (Fig 51) 2 V (Fig 35) 2 V (Fig 52) 12. In the second (1555) edition owing to the revision of text of the first (1543) edition some twenty replacements of initial letters (chiefly of the chapters) were made by the printer (e.g. E for O in chapter XI of book I; E for L in chapter XIII of book I).

Fig 78 *Institutiones Anatomicae* of Caspar Bartholin (1691)

blocks, and especially those of the larger series, are believed to have been done by Calcar, who also designed the anatomical plates

The initial letters present a full composition dealing with specific anatomical, medical, and surgical activity or with closely allied procedure or incident. The spaces behind the letters are completely filled with the composition. These decorative backgrounds fall into two simple and natural groups, namely, the preclinical and the clinical,¹ there are outdoor and indoor scenes.²

Considering first, the six large letters (Figs 30 to 35), the activities therewith depicted are varied. Cherubic curators secure an anatomical specimen in letter I (Fig 30) by robbing a grave, here, outdoors and against a background of masonry arches, the putti exhume a corpse—one holding a candle to illuminate the crypt, another keeping watch. Curiously, a soldier, present and seeming sympathetic, does not interfere with the scientific

Fig 79 *Opera*, of Ambrose Paré (Paris, 1582)

gathering of laboratory material. As background for the large initial L (Fig 31), and in the spirit of bawdy jest, one putto draws the reader's attention to the intestinal flux of his companion, whose afternoon's adventure in hawking must wait upon certain more fundamental matters. In the initial letter O (Fig 32), a skull is being cleaned in a cauldron which is suspended in a fireplace of ornate design, one putto works the bellows, another prepares to return the skull to the boiling pot, while a third appraises a long bone from which the soft tissues were previously removed. As a border ornament, around the oval letter, clustered leaves appear above, while griffon-like creatures give support from below. Similarly, as corner designs for the letter Q (Fig 33), winged cherubs appear above, their wingless counterparts are busy below, one of the latter idly sharpens a dissection-instrument while the other tests the sharpness of the tail of the letter Q. In the main scene, with the letter itself, eight well-nourished putti are about to carry out a cervical dissection on a pig, with the creature held to table by a chain through the mouth and rings about the legs, one

¹The following are preclinical Figs. 30 32 33 34 38 43 44 45 46 47 48 49 50 51 and 52. These are clinical Figs. 36 37 39 40 41 and 42.

²The following are indoor scenes Figs. 3 33 40 42 48 and 52. These are outdoor Figs. 30 31 34 36 37 38 39 41 43 44 45 46 47 49 50 and 51.

Fig 80 *Workes*, of Paré (London, 1649)

zealous putto wields the knife while a companion reads from a book of instructions. In the initial T (Fig 34), the cross-bar of the letter serves as the crude gallows on which a pig is being elevated for evisceration.

Different from all of the other initial letters, both large and small, is the V (Fig 35), which, first in the volume, heads the laudatory dedication to Charles V. In the highly ornamental background, between the arms of the V, Apollo and Marsyas are in contest for honors as the most skilled magician. As will be recalled, Apollo, having vanquished his opponent, thereby earns the right to do with Marsyas as he will. In the foreground, external to the V, stand the Muses (who have served as judges) on the reader's left, on the right, wearing the sash and crowned with laurel, Apollo now approaches his worsted adversary with purpose not as classical as it is anatomical.

Among the seventeen lesser letters there are scenes of clinical procedures as well as some which have to do with anatomic dissection and procure-

ment, and with experimental study. For the letter A (Fig 36), a corpulent putto submits to urethral exploration, he lies on a well padded bed, in the doubtful privacy of a glade. As the decorative scene for the letter C (Fig 37), four putti transport a rack employed in the reduction of fractures, trees, hills and steeped church appear in the conventional background. The motif of the initial letter D (Fig 38) is again anatomical, three cherubic morphologists saw open a skull, working in a spot somewhat secluded by crags and trees. The scene in the letter E (Fig 39) is again outdoor, putti are reducing a fractured leg, one racks and pegs the injured extremity, while his colleague prepares the restraining bandage. Similar treatment is depicted in the letter F (Fig 40), but the operation is carried out in a canopied room where the apparatus is more ambitious and, hence, less mobile, the patient sits on a low bed.

In a day of bludgeoning warfare, cranial fractures and massive contusions are common, and the frequency with which treatment is discussed and

TAB V

Figs 82 to 87 Works imitative of, or dependent upon, the *Fabrica* of Vesalius Illustrations of the abdominal organs in the male

Fig 82, above *Anatomia del Corpo Humano* of Valverde di Hamusco (1560)

pictured reflects the surgeon's need for instruction. So, it is not surprising to find such a scene among the historiated initials. In the embellishment of the letter H (Fig 41), there is shown the kind of cauterization which preceded craniotomy. The operation takes place against a background of castle and arch, the patient sits resignedly, one putto applies the iron, a second tends the fire, while two other juvenile "externes" are ready to perform less crucial tasks. Next, in alphabetical order, as a background for the letter I (Fig 43), an urethral examination and catheterization are pictured, the quarters are opulent, the important patient considerably pillowed, yet the putti are, traditionally, naked.

In the succeeding five letters (L to P) putti either garner or study anatomical specimens (Figs 43 to 47). For the letter L, against an austere background of unwooded hills, a corpse is lowered from a crude gallows into the arms of an avid putto (Fig 43). One of the latter's compan-

Fig 83 Pietro Berettini's *Tabulae Anatomicae* (Rome, 1741)

ions holds back a company of monks, in this lesser skirmish in the mediaeval war between Science and Theology. Here the artist was obliged to build a gallows, elsewhere the cross-arm of the letter T (Fig 51) conveniently subserved a comparable function. The letter M (Fig 44) is less lugubriously decorated. Unlike a scene from Hamlet, the background is a cozy town, the putti, here craftily busy on the outskirts of the village, inflate the stomach of an ox. In the N (Fig 45), they carry away a corpse for undisturbed dissection. In the initial letter O (Fig 46) an industrious gleaner prepares to hurry away from an execution, into his wicker basket the head of the victim is being dropped—in the presence of soldiers a horseback. For the letter P (Fig 47) there is provided a scene depicting curator's industry: the children assemble the bones of human skeleton, at the left an extremity has been articulated, while at the right an earlier stage is represented.

In the next four letters (Q to T, Figs 48 to 51), the activities pictured belong in the present-day

Fig 84 Felix Plater's *De Corporis Humani Structura et Usu*, Tab XXIX (Basil, 1603)

category of comparative anatomy. Within the medallion-space of the letter Q (Fig 48), five putti take part in the pelvic dissection of a dog, inquisitive cherubs dissect the head of an ox, enucleating the bulb of the eye from the orbital cavity (R, Fig 49), they bleed a dog (S, Fig 50). For the initial letter T (Fig 51), they string up a dog for purposes of experimentation, clubbing the helpless creature to death.

The alphabetical series closes with the letter V (Fig 52), which portrays a venesection, a juvenile surgeon incises the skin with a lancet, to reach a vein in the cubital fossa.

The initial letters of the index make up the third series (Figs 54 to 69). They are the smallest of the three sets, are least attractive, and bear little or no relation to the subject matter of the volume. Except for the A, they are of approximately uniform dimension (1.8 cm square), except for the letter Z, the set employed in the first edition of the *Fabrica* (Figs 54 to 61) was put

Fig 85 Johann Remmelin's *Catoptrum Microcosmi cum*, Adam figure (1619)

aside in favor of another lot for the second edition (Figs 62 to 69). Some of the blocks are remarkably clear (e.g., Figs 54, 66, and 67), others are so poor as to require hand-lens examination (e.g., Figs 64 and 65). Their decorative features are fabulous birds and mammals (Figs 54 and 55), cherubic musicians (Figs 57, 58, and 60), botanical herding and wayfaring, each finds its place in the groups (Figs 59, 62, and 65, respectively), one putto supports the Z (Figs 61 and 69), while another chin-rests upon the Y (Fig 68). Assumedly these initial letters of the indices were the printer's stock in trade—ready for use in any large volume whose proportions and promise warranted their employment.

The volume closes with a highly ornamental printer's mark (Fig 53). The colophon pictures Arion, poet and musician of ancient Greece. During a voyage at sea, the crew of the ship on which he sailed resolved to murder him for his money, and ordered him to jump overboard. Arion, having obtained permission to sing one song to the music of his cithara, threw himself into the sea. He was received miraculously on the back of a dolphin and carried safely to land. As so to Arion,

[illegible][illegible]

Besides there are two other scumblers that deflected to the end of this gape, being broad and membranous on each side - one arising from the side and inner parts of the throat and hip-bones, which inclined above the operator pull up the fundamental balling down - when forced they are called *lancers* and drive the lifers - *g* of the fundamental. Wherever when as either they are not weak, or relaxed, or the fundamental opposed with the weight of the epiglottis, false diaphragm and sharp membrane put is scarce returned into its place, but there is need of the help of the fingers for that purpose.

The next follow the sweepers of the stomach. Their action is the distributing the Chyle by the mesenteric vessels, which of duty belongs to the three small guts, (and the receiving the excrement of the Chyle and retention of them, till fit time of expulsion, which belongs to the third quarter. Besides, these small guts finish up the work of concoction, begun in the stomach, although they be not altogether made for that use. But nature is often accustomed to abuse the parts of the body for some better use.

The plot from the Harry Potter

Fig 86 *Workes of that Famous Chirurgeon Ambrose Parey*, p 82, chap XV of Liber 3 (1649)

as to all intrepid men, no way is impassable, gallantry sanguineously overcomes obstacles which are barricades to the white-livered and the shoddy

d IMITATIVE WORKS

Emulation is tribute in its unfeigned, since most practical form, and because Andreas Vesalius became the paragon of medical authors, it is clear that Vesalius' achievements were monumental. His *Fabrica* was the source for a long succession of less original writers of textbooks in anatomy and in related medical subjects. The text was overtly borrowed, adapted, or paraphrased, the illustrations were copied in wood and copper, they were converted into superimposed sets of layers, dressed in armour or put into waggish poses, they were rarely improved, often cheapened and debased.

Perhaps the most avaricious borrowers and most unscrupulous plagiarizers of Vesalian figures were the printers of the so called "Fugitive Sheets"

Fig 87 *Opera Omnia* of Boerhaave and Albinus, table from fifth book

These broadsides were printed and distributed in large numbers during the sixteenth and the first quarter of the seventeenth centuries. By their very character and wasteful use they were predestined to be scattered, as the term "fugitive" suggests. Because of their perishable nature, very few of them have survived. Some had superimposed flaps of the various organs, but in most instances the large cuts were surrounded by smaller elements and were accompanied by a descriptive text in Latin or in the vernacular of the country. It has been said that they were displayed in barber shops, apothecary shops and even in bathhouses, that they were printed and distributed to students as abbreviated substitutes for textbooks, and they were circulated among laymen to satisfy a perennial interest in the bodily organs.

Exclusive of borrowing for the fugitive sheets, the figures of the *Epitome* and the *Fabrica* were copied by more than twenty-five authors, whose

Figs 88 to 90 Works imitative of the *Fabrica*, continued. Illustrations of the abdominal and pelvic viscera in the female

Fig 88, above From Felix Plater, *Tabula XLII* (1603)

works passed, totally, through more than seventy-five editions (in Latin, French, Italian, Dutch, Spanish, and English).¹ Among the borrowers and imitators were Boerhaave and Albinus, Valverde, the Bartholins, Crooke, Rueff, R Emmelin and Pare.²

Following the pattern set by Vesalius in the *Fabrica* (Fig 70), Boerhaave and Albinus, in their *Opera Omnia*, copied the dissection scene in their

¹Among the authors of *sequelae*, the following have been named by authorities Maschenbauer, Leveing, Ravnsdal, Geminus, Baudin, Bauman, Boerhaave and Albinus, Bonavera, Botter, Fontanus, Fuchs, Van de Gracht, Moro and Montani, Pauw, Plater, Sandifort, Torteblat, Valverde, Parc, Bartholin, Kemmelinus, Crooke.

²In Dr Harvey Cushing's scholarly volume *A Bibliography of Andreas Vesalius* (New York: Schuman's, 1943) the illustrations and text of the several editions of the *Fabrica* and of its antecedents and *sequelae* are fully discussed.

As its title indicates the treatise contains a bibliography of Vesaliana (451 items) and an authoritative biography, whose portions are chronologically arranged in relation to Vesalius' preparation and publication of his anatomic work.

Fig 89 From Johann R Emmelin, Eve figure (1619)

title page (Fig 71). Valverde relegated a comparable scene to the base of his ornamental page, while bringing skeletons and experimental animals into greater prominence (Fig 72). Thomas Bartholin employed a full human hide to make an arresting title page (Fig 73). Crooke employed a similar device, but caused the stripped musclem to hold his own skin and the instrument used in removing it (Fig 74). Crooke also copied Vesalius' plan but added lesser scenes of surgical, biblical and moralistic character (Fig 75). Rueff introduced his midwifery with a title page which depicts a birth-chamber, complete with attentive nurses, hungry dog and bibulous servants (Fig 76). R Emmelin pictured scholars and the accouterments of knowledge (Fig 77). Caspar Bartholin exhibited the figures of the medically great—including, of course, Vesalius (Fig 78). Pare's title pages cover various subjects (Figs 79 to 81), the most appropriate being that which appeared in the English edition of 1649 (Fig 80).

Only when Calcar's drawings are compared with those in the *sequelae* does the full quality of the former become apparent. Two brief visceral sets (Figs 82 to 87, and Figs 88 to 90) demonstrate the excellence of the Vesalian illustration.

Juan de Valverde, in his anatomical plates, put the muscle-men to work. In one figure a brawny manikin holds suspended his own cutaneous coat, upright anatomical subjects draw aside the flaps of the abdominal wall with their own hands and lift the omental apron with their teeth, better to display their guts to the barber-surgeons of Seville. Not content with demonstrations of interior structures, Valverde dressed some of his subjects in partial armour, perhaps as a concession to the military trend of Spain's ambitions (Fig 82).

Berettini regrouped the pictorial material, to combine, in each of several plates, myological, nervous, and visceral elements, in one instance, figures of the intestines and stomach appear as bas-reliefs on block-like pedestals, while the flayed muscle-man holds a framed figure of a cervical dissection (Fig 83). Rueff limited his borrowing to illustrations of female pelvic anatomy (Fig 90). Plater adhered rather closely to the Vesalian arrangement of figures (Figs 84 and 88), as did Boerhaave and Albinus (Fig 87), both Remmelin and Paré altered the schema very considerably (Figs 85, 86, and 89). Because of the ingenuity exercised in the preparation of Remmelin's *Tabulae*, and the popularity of Paré's commonplace figures, the works of these writers call for special comment.

Of all the copied forms of the Vesalian *Fabrica*, that by Johann Remmelin displays the most ingenious craftsmanship. Remmelin, a physician of Ulm, artfully arranged the anatomical structures of the human body on plates in such a manner that parts lying at successively deeper levels were shown by means of pictures fastened one to the other like the pages of a book. These pages were published in 1613 under the title *Catoptron Microscopicum*. In this set of plates man (Fig 85) or woman (Fig 89) could view his microcosmic parts as if in a "mirror." The figures were frank copies of those in the *Fabrica*.

In the collected *Workes* of Ambroise Paré, descriptive material and figures were used, without notable replacement, through thirteen French editions, a Latin, and several English editions. The first edition (French) appeared in 1575, in Paré's sixty-fifth year. Editions succeeded each other in uninterrupted succession, to the thirteenth in 1685. Since the volume of collected *Workes* was a medicosurgical encyclopedia, its appeal was exceptionally wide. In being part of such a popular tome, the subject matter of the Vesalian *Tabulae*, debased to the status of figures in the text, was destined to be spread to every land where the influence of European medicine was felt. Anatomy was but a small part of Paré's

L I B E R

Fig 90 Jacob Rueff, *De Conceptu et Generatione Hominis*, second book (1580)

encyclopedic volume. He discussed dislocations and luxations, means of supplying an artificial nose, ivory teeth held in place by strings, a plate to fill a defect in the palate. He discussed the unicorn and opposed its use as an antidote against poisons, told eyewitness stories of plague-ridden towns, described monsters and prodigies, gout and the French pox, quackery, conception, birth, and the embalming of the dead.

6 GENERAL CONSIDERATIONS

In the 1555 edition of the *Fabrica*, as in the 1543, or first edition, ornamentation is lavish, the muscular figures stand effectively against old-world backgrounds, whose elements are the familiar bridges, rivers, and thatched houses of the Paduan environs, the superabundant initial letters are varied, their scenes pertinent, the title page, displaying a dissection scene in an amphitheatre of unexpected grandeur, is an exceptionally attractive introductory piece.

None of the imitative works equalled the *Fabrica* in respect to pictorial engraving. In Creigher's edition of the *Fabrica*, published in Venice in 1568, ornamental backgrounds are omitted, the muscle-men stand merely on plots of sparsely vegetate earth. The initial letters, poorly executed, are employed to head the chapters, they hold no relevancy to the text, being arabesques of conventional design (cf Figs 66 and 67). In the magnificent two-volume folios of Boerhaave and Albinus, published in 1725, for which Jan Wandelaar engraved the *Tabulae* in copper, the dissection-scene appears to particular advantage, as does also the likeness of Vesalius (frontispiece). In the grand full-page figures of the muscle-men, the backgrounds are retained, walled towns, tidy villages, winding paths, meandering rivers, hills and glades, austere mountains, mossy glens and Roman columns, stone bridges and ancient gates, lend such naturalness to the anatomic portraiture that the presence of a gracefully ambulatory specimen seems neither lugubrious nor doleful. Yet, despite the meticulous borrowing of the landscapes, the initial letters, used in all of the chapters of the several books, are merely flowered compositions, the pertinency which characterized the letters in Vesalius' works was sacrificed in the copied versions. Tailpieces, likewise irrelevant to the text material, are repetitiously employed.

In the work of Valverde (1560) the backgrounds are omitted, the muscle-men stand upon plots of hummocky, tufted ground. Initial letters appear in several of the full-page legends (facing the plates of illustrations), they are sparingly used in the text, to introduce each of the seven books, the chapters carry no initial letters. The chapter letters represent mariner, warrior, armorer, fabulous beast, and Neptune astride his sea calves—all in keeping with Valverde's martial display of the visceral specimen, clad in hauberk.

In the anatomies of Crooke and Paré, the title pages are distinctly ornamental. However, as in Valverde's volume, backgrounds are wanting. Initial letters are profusely used, introducing chapters, they match the *Fabrica* in their profusion. However, they are small arabesques of

the kind which might have been available in any busy printery. Headpieces and tailpieces, like the initial letters, bear no relation to the subject matter of the volumes.

In all respects, then, the *Fabrica* is an epochal work, as has been shown, the volume promptly became the repository, textual and pictorial, from which medical writers, less judicious, assiduous and ingenious than Andreas Vesalius, drew wholesale, or, like gleaners, took impatient and fragmentary excerpts. The greatness of the source is attested to by the inability of many of the copyists to maintain the standard set by the original work. Vesalius' *Fabrica* enjoyed the advantages offered by a volume of folio dimensions, his drawings were not required to take shocking reduction. The presswork was excellent, the engraved figures being superior to many reproduced by similar techniques in our own day. The collecting of Vesaliana long ago became a rewarding avocation among the world's medically great. The *Fabrica*, which is now complacently in the fifth century of its existence, is the pre-eminent nucleus for either a personal or institutional library of medical history.

Certainly the embellishment of the *Fabrica*, in the form of title page, historiated initial letters and ornamental background, adds greatly to its bibliophilic charm. The attractive initial letters record the interests and extramural occupations of the anatomist and the surgeon. In handling these subjects, the forbidding and the lugubrious aspects of professional endeavor are converted into pictorial witticisms—the latter note serving as a foil to set off the directly pedagogic objectives of the writer. In shunning the service that such decorations might perform for our modern textbooks, we have lost an opportunity to be subtly instructive and, at the same time, delicately appreciative of the humor of our faithful artists. Nurturing the misconception that scholarship ceases to be impressive when it is no longer stodgily sedate, we persistently fail to employ a device which sweetens textual fodder and supplies the surfeited reader with the alimantal juice of whimsy.

REVIEWS OF NEW BOOKS

THE first volume has been published of a series of books to be devoted to various methods and techniques used for experimental purposes. The governing board, consisting of Irvine H. Page, A. C. Ivy, Coltin H. MacLeod, Carl F. Schmidt, and David L. Thomson, state in the preface 4 reasons for this series of books: first, to give an appraisal and discussion of the various methods that have been proposed for experimental problems; second, to give a detailed description of methods; third, to give useful modifications of methods that are difficult to find in the literature; fourth, to make available many methods that were developed during the war and which have been described only in official reports. Each volume of *Methods in Medical Research*¹ will be divided into 4 or 5 principal sections, each of which shall, for that volume, represent one of the broad fields of medical research: biochemistry, physiology, pharmacology, microbiology, immunology, and biophysics including radiobiology. From these broad fields, various topics will be discussed by experts in that particular field.

The first volume is divided into 4 sections. Section 1, edited by Henry Welch, deals with the assay of antibiotics—penicillin, streptomycin, tyrothricin, bacitracin; it also includes tests for pyrogens, toxicity, and sterility of penicillin and streptomycin solutions and the histamine content of streptomycin. Section 2, edited by Harold D. Green, is concerned with apparatus and methods for the study of blood flow measurement in the circulation, such as, venous drainage recorders, mean flow recorders, pulsatile flow meters, perfusion systems, indirect methods for regional blood flow, collateral circulation, cardiac output and contractility, and cardiovascular activity. Section 3, edited by A. C. Ivy, concerns selected methods in gastroenterologic research including the assay of choleretic compounds, the preparation and use of the Mann-Williamson dog, and the study of gastric acidity in man. Section 4, edited by Van R. Potter, contains methods for the study of cellular respiration by means of measuring the respiration of intact animals and tissue slices by the homogenate technique, and by the analyses of tissue metabolites with *in situ* freezing techniques.

The book consists of 357 pages, it is well illustrated and contains many references. There are 2 indices, one for subject matter and the other of names cited throughout the book. It is an excellent source of information for anyone engaged in research work and will save a great deal of time in the development of a research problem. After the whole series is completed, the governing board may consider publishing

a volume each year dealing with the newer methods in all branches of biological research.

OPAL E. HEPLER

THE present accumulation of morphological, physiological, and clinical knowledge of each portion of the human body is now great, and almost beyond the comprehension of an individual student or of a practitioner in any single branch of medicine. This is specially true of the head, in which territory the general surgeon, the neurosurgeon and his colleagues in maxillofacial reconstruction, the otolaryngologist, the ophthalmologist, and the anesthetist find urgent demand for more precise and more dependable knowledge. Admittedly, this wealth of material often appears forbidding to the practitioner who desires to review the anatomy of the head and neck, and to the beginning student who may be preparing for a clinical specialty. For either, anatomic architecture must be regarded as basic.

The *Detailed Atlas of the Head and Neck*¹ offers the needed pictorial guidance. So complete is the series of pictures that it may safely be employed to replace the lesser sets of diagrammatized figures which have become the familiar, sometimes misleading, stock-in-trade of the specialist's library. Surface landmarks are emphasized, successively deeper anatomical layers and groups of structures are rationally portrayed, interrelationships are clarified. Not only are series of frontal and transverse sections through the most critical surgical levels included, but, in addition, regional dissections are abundantly illustrated, this combination facilitates the reader's acquirement of a serviceable appreciation of orientation and depth.

As Dr. E. A. Boyden points out in the deservedly laudatory introduction, the drawings in this fine work by Truex and Kellner were all made directly from original regional dissections, the same specimen being used in depicting the anatomy of each series. In order to insure the retention of proper proportions, either scaled enlargements or life-sized drawings were made. The illustrations in each series were uniformly reduced in publication, numerals, which accompany each figure, record the positive proportion to life size. The figures represent serial dissections from superficial to more deeply situated layers, and thus preserve a continuity, from one plate to the next, of the important structures within each region. This logical scheme not only permits visualization of the laminar relationships of fascia, muscles, bones, vessels, and nerves at each of the major cervical and facial levels, but also allows ready

¹METHODS IN MEDICAL RESEARCH. Van R. Potter, Ph.D., Editor in Chief. Vol. 1. Chicago: The Year Book Publishers, Inc. 1945.

¹DETAILED ATLAS OF THE HEAD AND NECK. By Raymond C. Truex, M.S., Ph.D., and Carl E. Kellner. New York: Oxford University Press, 1948.

review of the structures traversed, displaced, or excised in the course of the regional dissection. This method has been consistently followed for the anatomy of the neck, face, brain and spinal cord, orbit, ear, pharynx, mouth, larynx, nose, and paranasal sinuses. Additionally, axilla and thorax are handled with sufficient detail to demonstrate the continuity of the cervical organs, vessels, and nerves into the former regions.

Altogether, this volume must be hailed as exceptionally useful, its illustrations portray human structures as they are actually found in dissected and sectioned specimens, not as conveniently idealized or otherwise altered to match stereotyped illustrations of antecedent textbooks. It presents the kind of information which the present-day surgeon needs, and to the possession of which the medical student should early be introduced.

BARRY ANSON

IN the 11 years since Dr Means published the first edition of his book, *The Thyroid and Its Diseases*,¹ a mass of new knowledge about the thyroid gland has been accumulated. Most of this knowledge is in the field of thyroid physiology and has been gained through the use of two new tools (1) the antithyroid drugs, and (2) radioiodine. In spite of the overwhelming amount and complexity of the work with these agents, Dr Means and his collaborators have not enlarged the new edition to any extent. The new material has been assimilated and presented in its rightful place as a part of the whole thyroid picture.

As in the first edition, the writing is simple and straightforward. Many case histories are given to illustrate special points. Charts and graphs are liberally used. The approach throughout is mainly physiologic, yet the clinical picture is clearly set forth, and understanding of it is enhanced by the presentation of the physiologic basis. The completeness of the book has been furthered by the addition of chapters on pathology and tumors by Dr R. W. Rawson, and on surgery by Dr Oliver Cope. Dr Cope's chapter is detailed and contains many practical points for the thyroid surgeon.

The book is divided in much the same way as was the previous edition. The chapter which in the first edition was called "Simple Goiter" is now entitled "Goiters Due Primarily to Extrinsic Causes." Studies on radioiodine and on the goitrogens have pointed out the complexity of this group of thyroid disorders, and Dr Means has wisely dropped the term "simple" from his classification. The chapter formerly titled "Toxic Goiter" is now called "Graves' Disease" and a separate heading is given to adenomatous goiter with hyperthyroidism. Very little is said in the second edition about total thyroidectomy as a treatment for other diseases, a chapter was devoted to this subject in the first edition. "Nodular Goiter" and "Malignant Goiter" have now been combined

into a single chapter entitled "Tumors of the Thyroid." It is interesting also to compare the final chapter "Fact and Fancy in Matters Thyroid" in the two editions. Some questions raised in this discussion 11 years ago have been answered in full or in part, but they have been replaced, as usual, by further questions. The emphasis in the later edition is on physiology and relation of the thyroid to the body as a whole.

This volume is a stimulating dissertation. Each chapter in the book is followed by a concise summary and an inclusive bibliography. The index is excellent. A word of thanks should be given to the publishers for the improvement of the format of this edition over the previous one. As Dr Cope points out, "The surgeon who operates on the thyroid must have special knowledge of the gland, its action, diseases and environment." This statement holds true for anyone who undertakes the diagnosis and treatment of diseases of the thyroid. Dr Means' book contains this special knowledge.

W. M. BALFOUR

THE volume, *Acute Intestinal Obstruction*, is an easily readable 259 page book intended to acquaint the well trained surgeon with the known facts concerning gastrointestinal obstruction between the duodenum and the anus. A broad and very well documented review of the physiological aspects is exceptionally well done. For a work so well founded in the older literature on this subject there is unfortunately a none too strong survey of the physiological and therapeutic developments of the past few years.

There is a reference list of some 350 titles, 2 being case reports of the author's. Rather free reference to many of the workers listed in the bibliography is made, but there is considerable ambiguity in the text as to the origins of the techniques described. Procedures are included which have been abandoned by most students of the subject, and some of the recent excellent contributions are not yet included.

This is a very informative book for the casual reader, and a thought-provoking one for the thoroughly experienced surgeon. The shortcomings indicated above, however, unfortunately render it an incomplete guide in the training of the abdominal surgeon.

CLARENCE DENNIS

THE new American text *Bacterial and Mycotic Infections of Man*² is published as a companion volume to Rivers' edition of *Virus and Rickettsial Infections*. There are 34 contributors to the 37 chapters. All of the authors are acknowledged leaders in

ACUTE INTESTINAL OBSTRUCTION. By Rodney Smith M.S. F.R.C.S. With a chapter on radiological diagnosis by Eric Samuel M.D. F.R.C.S. F.F.R. D.M.R.E. Foreword by Rupert Vaughan Hudson F.R.C.S. Baltimore. The Williams & Wilkins Co. 1948.

BACTERIAL AND MYCOTIC INFECTIONS OF MAN. Edited by René J. Dubos Ph.D. Philadelphia London and Montreal J. B. Lippincott Co. 1948.

¹THE THYROID AND ITS DISEASES. By J. H. Means M.D. 2d ed. Philadelphia London and Montreal J. B. Lippincott Co. 1948.

their chosen field of fundamental research. Each of the chapters presents a precise summary of current investigation in a way that is possible only under the plan of group authorship.

The opening chapters are devoted to an exposition of host-parasite relationships, bacterial morphology and physiology, and the principles of immunity and allergy. Especially outstanding are the sections on bacterial morphology and physiology by Dubos and Pappenheimer and on the allergic state by Chase.

Excellent coverage is given to the bacteria of proved or probable pathogenicity to man. Adherence to the taxonomy adopted in the latest edition of Bergey's *Manual* represents a forward step for clinical bacteriology to follow. Homer Swift's section on the streptococci is excellent, as is Blair's handling of the staphylococci, and Mueller's discussion of diphtheria. The completeness of this portion of the book may be emphasized by reference to the splendid summary of the current studies upon *Streptobacillus moniliformis* and the pleuropneumonia group by Sabin.

The precedent set by Hiss and Zinsser for inclusion of chapters on mycotic infections in bacteriologic texts has been adopted. Conant's sections on the actinomycetes and the fungi imperfecti are concise and clear. Separate handling of the Wolff-Israel bacillus and the nocardia follows American custom and clinical practice.

The concluding chapters embrace a variety of subjects including the technique of bacterial identification, principles of sterilization, and a brief résumé of antibiotic and chemotherapeutic agents. One feels that limited space was assigned to these subjects to gain complete textual coverage. The compromise which has been made is disappointing. Another criticism of the text is the brevity of the sections on the clostridia.

The book is to be regarded as a valuable and thoroughly up to date review of academic and investigative bacteriology. It has all the qualifications of a text for students of bacteriology and should appeal to the clinician as a reference in the thoughtful contemplation of clinical problems in specific infections.

CHAMP LYONS

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

DALLAS B. PHLEMISTER, Chicago, *President*
FREDERICK A. COLLIER, Ann Arbor, *President-Elect*

PRELIMINARY PROGRAM FOR THE 35th CLINICAL
CONGRESS—THE STEVENS, CHICAGO,
OCTOBER 17 TO 21, 1949

WILLI hotel headquarters at The Stevens, the thirty-fifth Clinical Congress of the American College of Surgeons will be held in Chicago from October 17 to 21, 1949. On the last day, October 21, the Sixth Inter-American Congress of Surgery, for which the Clinical Congress will be host, will open a three-day series of sessions. The plans for the Inter-American Congress are described in a separate article. The American College of Surgeons is a member of the Association of Inter-American Congresses of Surgery.

Operative and nonoperative clinics will be held in some twenty hospitals in the Chicago area each day during the Clinical Congress. The hospitals which will participate in the clinical program are approved by the American College of Surgeons for graduate training in surgery. The schedule of clinics, which will cover general surgery, obstetrics and gynecology, fractures and other traumas, orthopedic surgery, thoracic surgery, neurosurgery, genitourinary surgery, and ophthalmology and otorhinolaryngology, will be published in a *Daily Clinical Bulletin* which will be issued each day during the Clinical Congress. The clinic schedules will also be posted on bulletin boards.

Operations will be telecast, in color, to the hotel from one or more of the hospitals at scheduled periods each day. The successful demonstrations of television at the Clinical Congress in New York in 1947, and at the Clinical Congress in Los Angeles in 1948, make it highly desirable to continue the use of this medium. Television has proved itself to be an ideal means of furthering the "Show me" purpose which was the main incentive for the founding of the Clinical Congress of Surgeons of North America in 1910, three years before the American College of Surgeons was organized. That first Clinical Congress was held in

Chicago. The 1949 meeting will be the ninth held in that city.

A varied and comprehensive program of meetings will be held at the headquarters hotel. A general assembly for both surgeons and hospital personnel will be the opening session on Monday morning, October 17. Scientific sessions, official meetings, hospital conferences, showings of medical motion pictures, and telecasts will follow during the five days, and many surgeons will undoubtedly wish to remain for the sessions of the Sixth Inter-American Congress of Surgery on Saturday and Sunday. Delegates and visitors to the latter meeting will likewise be welcome at clinics and other sessions of the Clinical Congress of the American College of Surgeons. All will be interested in the extensive display of technical exhibits in the exhibition hall on the lower level and in the scientific exhibit on the mezzanine floor of the hotel.

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening, October 17. At this meeting the officers-elect consisting of Dr. Frederick A. Coller of Ann Arbor, president, Dr. Donald G. Tollefson of Los Angeles, first vice-president, and Dr. Robert M. Moore of Galveston, second vice-president, will be installed. The outgoing president, Dr. Dallas B. Phlemister of Chicago, will preside and will deliver the Presidential Address.

Sir James R. Learmonth of Edinburgh will deliver the fourth Martin Memorial Lecture. His subject will be "Collateral Circulations, Natural and Artificial."

CONVOCATION

The formal initiation ceremonies for the new Fellows will be a colorful feature of the annual Convocation which will be held on the final evening, Friday, October 21. Honorary fellowships

will also be conferred on this occasion Lord Webb-Johnson of London, president of the Royal College of Surgeons, will deliver the Fellowship Address

EVENING SCIENTIFIC SESSIONS— GENERAL SURGERY

The program and speakers for the Tuesday evening general surgery session will be as follows
Symposium—Acute Surgical Emergencies in Gynecology and Obstetrics

General Introduction NEWELL W. PHILPOTT, M.D., F.A.C.S., Montreal

Tubal Pregnancy, Its Diagnosis and Treatment LEWIS C. SCHEFFEY, M.D., Philadelphia

Pelvic Peritonitis Occurring in the Obstetrical or Gynecological Patient FRANK GLENN, M.D., F.A.C.S., New York

Emergency Cesarean Section WILLIAM E. STUDDIFORD, M.D., F.A.C.S., New York

The program and speakers for the Wednesday evening general surgery session will be as follows
Fracture Oration Fracture Hazards OTTO J. HERMANN, M.D., F.A.C.S., Boston

Symposium—Blood Coagulation and the use of Anticoagulants

The Significance of Different Methods for Prothrombin Estimation and their Relative Values JOHN H. OLWIN, M.D., Chicago

Studies on Antithrombin and Etiologic Factors in Phlebothrombosis JOHN H. KAY, M.D., New Orleans

A Further Report on Dicumarol Prophylaxis against Venous Thrombosis in Women Undergoing Surgery GEORGE VAN S. SMITH, M.D., F.A.C.S., Brookline, Massachusetts

The program and speakers for the Thursday evening general surgery session will be as follows
Symposium—Malignant Disease

Chemotherapy in Malignant Neoplastic Disease CARL V. MOORE, M.D., St. Louis

Hormone Therapy of Cancer CHARLES B. HUGGINS, M.D., Chicago

The Use of Radioactive Iodine in Studying the Pathologic Physiology of Thyroid Cancer RULON W. RAWSON, M.D., New York

What We have Learned from Isotopes Concerning Depletion and Repair in Surgical Patients FRANCIS D. MOORE, M.D., F.A.C.S., Boston

GENERAL SURGERY PANEL DISCUSSIONS

General surgery panel discussions will be held on Monday, Tuesday, and Wednesday afternoons,

from 1:30 to 3:00 and from 3:30 to 5:00 o'clock. The subjects and the names of the moderators follow

Monday—1:30 to 3:00 p.m.

Surgical Lesions of the Breast GEORGE G. FINNEY, M.D., F.A.C.S., Baltimore

3:30 to 5:00 p.m.

Fractures of the Skull ELDRIDGE H. CAMPBELL, M.D., F.A.C.S., Albany

Tuesday—1:30 to 3:00 p.m.

Massive Upper Abdominal Hemorrhage JOHN H. MULHOLLAND, M.D., F.A.C.S., New York

3:30 to 5:00 p.m.

New Surgical Technique in Drug Treated Infections CHAMP LYONS, M.D., New Orleans

Wednesday—1:30 to 3:00 p.m.

The Management of Acute Emergencies Occurring During Operations I. MIMS GAGE, M.D., F.A.C.S., New Orleans

3:30 to 5:00 p.m.

Preoperative and Postoperative Care and Anesthesia for Infants THOMAS H. LANMAN, M.D., F.A.C.S., Boston

SPECIALTY SESSIONS

Plans will be announced later for the sessions in ophthalmology, otorhinolaryngology, orthopedic surgery, plastic surgery, urology, thoracic surgery, neurological surgery, and obstetrics and gynecology. Friday afternoon will be devoted to panel discussions in the surgical specialties, but a definite schedule has not yet been completed for other sessions.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems will be held on Monday through Thursday afternoons, and Tuesday through Friday mornings. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented, under the general direction of Dr. Owen H. Wangenstein, chairman of the committee, Forum on Fundamental Surgical Problems.

HOSPITAL CONFERENCES

The twenty-eighth Hospital Standardization Conference will be held during the first 4 days of the Clinical Congress. Its opening meeting will constitute the first formal session of the Clinical

SIXTH INTER-AMERICAN CONGRESS OF SURGERY

THE thirty-fifth Clinical Congress of the American College of Surgeons will be host to the sixth Inter-American Congress of Surgery when it convenes in Chicago on October 21, 22, and 23. On its first day it will overlap with the Clinical Congress. The delegates and visitors from Latin American countries will be welcome to attend all sessions of the Clinical Congress, and the operative clinics at the hospitals.

The American College of Surgeons joined the Association of Inter-American Congresses of Surgery by vote of the Board of Regents on June 27, 1944.

This action was preceded by an invitation from Dr. Luis Vargas Salcedo of Santiago, Chile, dated July 21, 1942, to send two delegates as guests of honor to the first Inter-American Congress of Surgery in Santiago, held November 14 to 19, 1942. Dr. Leo Eloesser attended as delegate, and it was upon his enthusiastic recommendation that the College accepted the invitation to join. He also attended the second Congress held in Buenos Aires, October 10 to 15, 1943. Dr. Alton Ochsner was delegate to the third Congress, held in Rio de Janeiro from September 6 to 15, 1947. The fifth Congress was held in La Paz, Bolivia, October 17 to 21, 1948, with Dr. E. Payne Palmer of Phoenix and Dr. Hu Crim Myers of Philippi, West Virginia, as delegates and co-relators.

The surgical societies of the following countries, in addition to the United States, are members of the Association of Inter-American Congresses of Surgery: Argentina, Brazil, Bolivia, Chile, Cuba, Ecuador, Mexico, Panama, Paraguay, Peru, and

Uruguay. Dr. Arnaldo Caviglia of Buenos Aires is the Secretary-General.

A preliminary outline of the program for the Sixth Inter-American Congress of Surgery follows:

Friday morning, October 21

Inaugural Ceremony

Friday afternoon, October 21

Delegates may attend the specialty panels of the Clinical Congress

Saturday morning, October 22

Main Theme: Acute Craniocerebral Trauma

Relator: E. Jefferson Browder, M.D.,
F.A.C.S., Brooklyn

Co-relators: To be appointed by each country

Saturday afternoon, October 22

Main Theme: Treatment of Injuries in the Region of the Ankle with Complications and Sequelae

Relator: Harrison L. McLoughlin, M.D.,
F.A.C.S., New York

Co-relators: To be appointed by each country

Saturday evening, October 22

Official Banquet

Sunday morning, October 23

Business Session

Sunday afternoon, October 23

Main Theme: Pulmonary Carcinoma

Relator: Everts A. Graham, M.D., I.A.C.S.,
St. Louis

Co-relators: To be appointed by each country

COLLECTIVE REVIEW

NEUROLOGICAL SURGERY THROUGH THE YEARS OF WORLD WAR II

LOYAL DAVIS, M D , F A C S , Chicago, Illinois

NEUROLOGICAL surgery received its greatest impetus from two sources. The first was a great personality who chose that field of surgery for his life's work and whose intellect, ability, capacities, and idealisms quickly called attention to the opportunities for surgical therapy and research which challenged solution. The second was the occurrence of World War I and the large number of soldiers who suffered from injuries of the brain, spinal cord, and peripheral nerves.

The many contributions made to surgical progress by the men who devoted their energies to the problems of neurological surgery in the interim between the end of World War I and the beginning of World War II laid the foundation for the expectation of better results than were compiled in 1918. It appeared likely that improvement would depend on newly acquired and more widely practiced surgical skills and upon the new antibiotics which seemed to offer such great assistance in meeting the challenge of compound wounds of the nervous system. It was hoped that the confusion and failures of the military medical services in World War I in assimilating the necessary and tremendous numbers of civilian doctors suddenly brought into their corps would be avoided by 25 years of peace in which their leaders would have been able to work out a smooth organization.

ORGANIZATION

Between World Wars I and II the British Army had recognized neurological surgery as a specialty and, after Munich, plans had been formulated for utilizing in the most efficient way the limited number of neurological surgeons available to the Army. This was accomplished by the appointment of a Consultant Neurological Surgeon to the Director General of the Army Medical Services, who made the policies and assigned responsibilities, as he desired. He was not tied to a desk at the War Office, but, on the contrary, had the greatest freedom in keeping in touch with patients, with university research which was applicable to neurosurgical problems, and with neurosurgical trainees. At the same time the Consultant was able to maintain close contact with the Director General and his group of administrators at the War Office.

In contrast, the American Army was decentralized into theaters of operation, in one of which there was a Consultant Neurological Surgeon and in two of which the responsibility for the direction of neurosurgical policy was assumed by the general surgical consultant. A neurosurgical consultant to the Surgeon General in the zone of the interior functioned only through the Chief Surgical Consultant. All of these individuals acted separately and, as a matter of fact, liaison and consultation between them on neurosurgical policies was actively discouraged. The neurosurgical consultant in a theater of operations was therefore independent and unaware of the policies for the

Department of Surgery Northwestern University Medical School.

cause the tables of organization in the forward hospital units made no provision for neurosurgical operations. In the zone of communications, neurosurgeons were attached to general hospitals but often under the appellation of "septic" or "aseptic" surgeon. In the zone of the interior, a neurosurgeon with a properly equipped service was established in the large general hospitals. Neurosurgical teams consisting of a qualified neurological surgeon, an assistant, anesthetist, nurses, and orderlies were a part of a large auxiliary surgical group, and many of the teams were assigned to evacuation hospitals, which were fixed large bed units, without proper flexibility or mobility. No neurosurgical unit in the Army of the United States had a trained neurologist assigned to it as one of its component members. Cairns has said, "At all levels of neurosurgical work in the Army (British) co-operation of neurologists and neurosurgeons proved to be essential." The observations of Ritchie Russell and his colleagues upon the sensory disabilities resulting from lesions of the parietal cortex are invaluable. That neurologists and neurological surgeons can co-operate in the American Army and produce a successful result is attested to by the contributions which came from the combined electrodiagnostic and electromyographic study of peripheral nerve injuries which was carried on in one of the large general army hospitals in the zone of the interior. Part of the responsibility for the failure to use neurologists properly in World War II by the Army of the United States must be laid, where it belongs, upon the apathy and almost total lack of interest exhibited by the neurologists of this country in presenting the opportunities for service to the wounded and in research which their specialty could offer. The specialty of neurology in World War II was completely overshadowed and many of its leaders were overwhelmed by psychiatry. Whether or not the latter specialty will have made any lasting contribution to either the care of the wounded or the civilian population as a result of experiences in the war still remains to be proved.

The National Research Council organized committees in the various fields of medicine and surgery under the auspices of the Office of Scientific Research and Development. Contracts were made between the latter and responsible investigators usually associated with medical school faculties, for financial grants to aid research which was deemed to be of value in prosecuting the war. On the whole, the application of the results of the research was quite direct. The Subcommittee of Neurosurgery was established under the Com-

mittee of Surgery and was very active in stimulating and encouraging research that yielded results which were of value to the war effort in the care of the wounded.

It is questionable whether the organizational problems and difficulties encountered by the civilian medical profession, when it was called upon suddenly to assume the tremendous responsibilities of World War II, will be avoided in any future conflict. The bureaucracy of the War Department does not learn its lessons easily and, even if it did, its inflexibility is stupendous. The only hope is that there will be in peacetime a sufficient number of alert, intelligent, and aggressive doctors in the regular army medical corps who will keep abreast of the advances in medicine and who will be receptive to the requirements of the civilian doctor when he is called to war. The civilian professional in every specialty in turn must do his share to educate the regular army medical officer to the needs of progressive medicine in time of war.

CRANIOCEREBRAL WOUNDS

That the brain and meninges were able to resist infection to a remarkable degree was a fact that had been learned in World War I. The fact that Cushing recognized that it was usually infection which had defeated him in the surgical treatment of head wounds, that is, meningitis, abscess, and encephalitis, did not change that fundamental fact. Consequently, in the last war the problem was one of assisting the brain to exercise this power, perhaps by more expert handling and by intelligent use of the newly discovered antibiotics.

In World War I, Cushing's mortality in moderately deep head wounds was 36.6 per cent, in the cases in which the ventricles were opened it was higher, while in through-and-through wounds of the head and in the wounds of the brain which also involved the paranasal sinuses or the mastoid, the mortality was from 70 to 80 per cent. Jefferson estimated that of 28 of his own patients in World War I with head wounds, only 4 had died because of the irrecoverable nature of the brain injury itself. In all the others death was due to infection. In World War II not only did a larger number of patients with head wounds survive but, what is more significant, the percentage rate of primary healing, which is so important in these wounds, was about 85 per cent.

Anaerobic infections, particularly gas gangrene, had overwhelmed the surgical procedures in World War I, and it was thought likely that penicillin and the sulfonamides would not be the com-

plete answer to the invading clostridial organisms present in cultivated earthy soils. The reports of the British 21st Army Group, which fought in World War II over the same area in which many of World War I battles took place, showed that gas bacillus infections were not as frequent as they had every right to expect from the reports of the 1914-1918 experiences. In 11 months a total of only 356 such infections was encountered, and the recovery rate was 78 per cent.

Graschenko studied the bacteriology of cranio-cerebral wounds in the Red Army and stated that after 3 to 4 weeks, 12 per cent of the wounds showed a flora of pathogenic anaerobes, 20 per cent showed aerobes, 70 per cent showed cocci and from 8 to 10 per cent were infected with putrid anaerobes. Of the 203 per cent of patients in whom pathogenic anaerobes were found, 14 per cent died in 6 or 7 days of severe gas gangrene infections. Subacute anaerobic infections of the brain were found in all large brain fungi, and of 12 patients with such infections, 9 died. Thirty-two cases of chronic anaerobic infection of the brain were studied and among these there were 10 deaths. Among 34 cases of mild anaerobic infection of the brain which were studied there were no deaths. Graschenko found the *Clostridium perfringens* (*Clostridium welchii*), *Clostridium sordelli*, *Clostridium fallax*, *Clostridium oedematiens*, *Clostridium oedematiens maligni*, and the *Streptococcus anaerobicus* to be the prevalent anaerobic organisms. A polyvalent serum was used against gas gangrene infections which contained the *Clostridium histolyticum*, *Clostridium perfringens*, *Clostridium oedematiens*, and *Clostridium oedematiens maligni*. Prophylactic doses of 10,000 international units were given intramuscularly and therapeutic doses of from 30,000 to 40,000 units were used intravenously and intramuscularly. When the surgical mission to Russia visited Moscow in 1943, Graschenko had at his disposal gramacidin, but not penicillin. The sulfonamides were used intravenously, and in 1 case 10 c.c. of an 0.8 per cent solution were injected into the spinal fluid every day for 12 days with a successful recovery and without damage to the patient. Sulfathiazole, sulfanilamide, and streptocide (sulfapyridine) were then available.

Surgical technique. In World War II, suction, electrosurgical apparatus, and the hemostatic agents, such as fibrin foam and gelatin foam, were the outstanding technical contributions to surgery which aided the neurological surgeon. The principles of excision and primary suture which had been laid down by Cushing and others were the

basis upon which the treatment of uncomplicated wounds of the brain was evolved. Early in the war, many head wounds which were partly excised in the forward areas of the British Army were then seen after more than 1 week following the injury at the neurosurgical units. Ascroft reported upon 276 patients with brain wounds who were treated in the Middle East, in 1943, 75 of these developed brain abscess and many required more than one additional operation before they could be cured of the infection. He showed that in a high proportion of these cases, retained bone fragments in the brain were the cause of the abscess. He advised immediate reoperation upon all patients of whom the x-ray films of the skull showed bone chips or a single large chip present in the brain, even if the external wound had healed primarily and the patient was free of symptoms. Obviously, retained macerated cerebral tissue, which made a peculiarly favorable media for the growth of bacteria, was also retained with the bone chips. This principle, however, was confirmed time and time again in the American army. When the British neurosurgical units, with their extreme mobility, received their head wounds early and performed meticulous excision of the wounds, they closed them and obtained healing per primam. The incidence of postoperative infection and any need for second or third operations decreased. As time went on the importance of an incomplete débridement of a wound track with resultant hematomas and eventual respiratory embarrassment was more and more apparent.

In World War I Cushing had emphasized the tripod incision for repairing scalp defects. In World War II, advancements in the field of plastic surgery pointed the way for the use of sliding and rotation flaps of the scalp to cover a defect produced by thorough excision of a scalp wound. This materially reduced the incidence of cerebral fungus and good healing resulted, so that eventually the tripod or relaxing incisions were abandoned.

Fascia lata and pericranium grafts and, later, fibrin film, were used to close defects in the dura mater. It was found necessary to close penetrating wounds which involved the paranasal sinuses, and large defects in which postoperative herniation of the brain would be followed by serious cerebral damage. German neurosurgeons advocated the routine closure of all dural defects to prevent postoperative infection and the formation of a fungus. This procedure was followed by some inexperienced American neurological surgeons to the point of absurdity, but the experi-

enced American neurological surgeon confirmed the fact, first established by the British, that careful excision of the wound and meticulous closure of the scalp were the most important factors in preventing postoperative infection, and not closure of the dura mater, except in the instances mentioned above.

Martin and Campbell clearly stated the principle concerning the use of drainage in craniocerebral wounds. Their view was that in deeply infected wounds of the brain a drain was unnecessary if débridement was done thoroughly, but if débridement was not complete a drain did not suffice. There was some disagreement with this viewpoint, nevertheless in the closing stages of the war the use of drainage became less common.

The operative treatment of craniocerebral wounds may be summarized by saying that it was based upon an ever increasing ability of the surgeon to cleanse and débride the track of the wound thoroughly. Closure of the scalp and dura with more extensive employment of technical methods of plastic surgery was an evolution which materially affected the successful results obtained. Whereas in World War I the wound track was débrided and cleansed by syringing, in World War II the track of the wound was visualized and cleansed by suction with emphasis upon the removal of all foreign materials, blood clots, and pulped brain tissue. It was concluded that these materials were far more dangerous than the risk of spreading contaminated material through the brain at operation. In World War I the dictum was that wounds more than 24 hours old should be packed open, which in fact was followed in other wounds of the body in World War II. Seriously contaminated wounds of the brain and other wounds seen 3 days after injury or even later were closed after complete cleansing and débridement. Purulent wounds were also closed completely by the British with a small tube left in place for the introduction of penicillin.

Chemotherapy It has become a trite statement that the sulfonamides and penicillin are not substitutes for meticulous surgical procedures. However, there are those craniocerebral wounds in which pathogenic organisms gain access to the subarachnoid spaces or ventricular system regardless of the care with which operative procedures have been carried out. Toennis reported a large series of deaths in the German army from infection of the brain and its meninges after wounds of the paranasal sinuses. Cushing and his team in France in 1917 lost almost 1 of every 3 patients from ventriculitis, meningitis, or some other type of brain infection.

Cairns and his colleagues advocated the use of 18 gm of sulfadiazine on the first day and 12 gm daily thereafter in the treatment of meningitis. In fact, this drug was used as a prophylactic measure. It is obvious that the proper pH of the urine must be maintained to avoid renal complications, and it has been found that this can be accomplished best by the intravenous administration of N/6 sodium lactate solution. Powdered sulfonamides had been applied locally to brain wounds and Ascroft reported no ill effects therefrom. However, Pilcher and others in America showed that sulfathiazole, particularly, produced convulsive seizures when applied directly to the brain. Isotonicity and neutrality are the important factors when any substance is brought into contact with the brain.

Cairns and his colleagues also established that penicillin given intrathecally is successful in the treatment of meningitis from organisms susceptible to penicillin, provided of course that there is no block in the cerebrospinal fluid pathway and that the source of the infection has been adequately treated. They showed also that in grossly infected wounds with superficial suppuration, cellulitis of the scalp, osteomyelitis of the skull, and infected brain fungus, systemic administration of penicillin is of great value. Contrary to the workers in America, they saw no convulsive seizures develop from the intrathecal or intraventricular use of penicillin when the proper dosage was given. The work of Wyck in Australia confirms these findings, as do experiences with individual patients presenting pneumococcal meningitis in civilian practice. The relative value of local and systemic administration of penicillin in the prevention of gram-positive infections after the excision and suture of brain wounds was not completely proved by Cairns and his co-workers, but it must be emphasized that it was the facility with which Cairns, the Consultant in Neurological Surgery to the British Army, moved about, saw results first hand, and had the opportunity to encourage and stimulate his younger colleagues in their work that made these valuable fundamental contributions possible.

Penetrating wounds and retained missiles In an attempt to determine the exact course of events in penetrating wounds of the brain, Pilcher studied a group of dogs into the heads of which unsterile foreign bodies penetrating the ventricle and still protruding through the skin invariably produced a rapidly spreading and fatal infection of the meninges, brain, and ependymal lining of the ventricles. If a foreign body was removed within 12 hours the incidence of fatal infection was

greatly reduced. Failure of the foreign body to reach the ventricle greatly reduced the likelihood of death from a fulminating infection. Pilcher concluded that an unsterile foreign body, deeply imbedded but not communicating with either the skin or the ventricle, does not cause fatal infection unless at some time the ventricle was penetrated. His experiments, therefore, showed that a foreign body communicating with the skin, subarachnoid spaces, or ventricle should be removed as early as possible, but if the object is located deep within cerebral tissue and does not communicate with the ventricle or the outside, it is usually best to leave it in place unless local destructive symptoms develop. In the British Army, missiles in the brain were removed in less than one-third of the cases in which they were present. Ascroft, in 1943, concluded that it was retained bone chips rather than the retained missile which gave rise to a brain abscess, but later in the war the occurrence of abscess about a missile, although the bone chips had been completely removed, was frequent enough to direct closer attention to removal of the missile. Electromagnets were replaced for the most part by the simple procedure, advocated by Schorstein, of using a piece of magnetized steel held in a pituitary rongeur.

Relatively speaking, the occurrence of intracranial hematoma is uncommon in missile wounds of the brain. Ascroft reported that intracranial hematoma caused death in 13 of 359 fatal cases of brain wounds. Schorstein reported 57 recoveries in 83 cases and called attention to the fact that hematoma occurred most often as the result of small penetrating missiles of high velocity when the wound of entry was too small to allow escape of the clot.

Reference has been made to the experience of the German army, that brain wounds which involved also the paranasal sinuses were overwhelmingly fatal. In civilian neurological surgery the problem of closing a dural defect of the anterior fossa which communicated with the frontal sinuses had been attacked in several ways and its importance was widely recognized. At the Head Injuries Hospital in Oxford, England, during World War II, 400 operations were performed for closure of the torn dura over the paranasal sinuses. As experience increased it was found there that intradural repair with fascia lata through an osteoplastic flap was the most satisfactory method. However, each wound presents a specific problem and often exenteration of the sinuses or an extradural method of repair proves more effective. The time and place for such operation, which are time consuming if they are performed as they

should be—with meticulous regard for details—may be difficult to prescribe in war injuries. Certainly, they should not be undertaken routinely under less than ideal conditions, as they were in some units of the American army.

Repair of skull defects. In the American army it became the policy early during World War II to repair skull defects by the use of various types of material, but finally tantalum was most widely used, while acrylic resin was less frequently employed. In civilian life prior to World War II, several neurological surgeons had employed acrylic resin in several instances and found it to be quite satisfactory. There was no established policy for the repair of skull defects as far as size and location of the defect, the time and place for repair, or the symptoms which indicated the need for skull repair were concerned. As a result, small defects of the skull without accompanying symptoms of any kind were covered with a tantalum plate as frequently as large defects in the frontal area with accompanying loss of the orbital ridges. In only one Army general hospital in the United States were preoperative encephalograms or ventriculograms taken to provide an accurate record of the state of the ventricular system and subarachnoid spaces before the tantalum plates were applied. The policy regarding resection of the underlying scar of the brain varied with the individual neurological surgeon from resection of the brain down to the underlying ventricular wall to no interference whatever, not even dissection of the dura mater away from the overlying edges of the defect. In no Army general hospital were postoperative air studies performed as a part of the procedure of closing skull defects. Therefore, in the majority of instances the operation became a mechanical one of carpentry. As a result, the effect of closing skull defects by plastic methods upon the occurrence of epilepsy following head wounds, or the change in status of the ventricular and subarachnoid systems following the operation will never be accurately determined in the American wounded. Neurological surgeons now engaged in service in the Veterans hospital facilities are obliged to remove tantalum plates from the skulls of patients in whom they were placed unwisely because of persisting infected and draining sinuses and osteomyelitis of the surrounding bone. The advantages of acrylic resin over tantalum on x-ray studies of the ventricular and subarachnoid systems are obvious.

Posttraumatic convulsions. The frequent occurrence of convulsive seizures following craniocerebral injuries of warfare has been a matter of great concern since World War I, as Schmidt pointed

out In some patients the injury to the brain is so great that regardless of their care, convulsions may be expected to occur In others, unwise surgery, particularly injudicious zeal in extracting an indriven missile with no regard for the destruction required to remove it, or infection of the brain, meninges, and skull may be etiological factors Ascroft reviewed the case histories of 317 patients who received cerebral gunshot wounds in World War I in 1941 One hundred seven of these patients suffered from convulsive seizures 4 years or more after receiving their wound Thirty-three of this number were having major convulsions with a focal onset, frequently an aura Many cases of petit mal seizures were of a focal character Attacks were twice as frequent in the cases of cerebral injury in which the dura mater was penetrated, compared to the cases of injury without dural tears Patients from whose brains metallic foreign bodies had been removed were much more commonly subject to convulsions than patients who had not undergone such surgery at the time of their injury or who still retained the missile Scalp wounds of all kinds were followed by convulsions in 24 per cent of the patients, probably because of the more severe underlying brain injury than that occurring with the usual scalp injury in civilian life Ascroft also found that although convulsions more certainly follow direct injury to the sensorimotor cortex than injury to some area removed from the rolandic area, yet the exact site of cortical damage did not seem to have such an important bearing on the production of convulsions The first seizure might occur within a few hours or as late as 20 years after the original injury, but usually the onset of convulsions was sometime during the first 2 weeks after injury

Protection against craniocerebral injuries According to Cairns, little work was done on the protective value of the steel helmet against craniocerebral wounds However, there were many individual cases in which what would probably have been a penetrating wound presented itself as a simple wound of the scalp and skull because of the helmet Cairns perfected and had adopted a protective helmet which was worn by motorcyclists in the British Army, and its value was demonstrated on many occasions

The regular issue steel helmet worn by the American soldier admittedly furnished excellent protection against craniocerebral injuries However, it was not designed for the use of the crews of aircraft or tanks and could not be used to advantage by them, mainly because of its size, shape, and weight Nevertheless, the desire of

one copilot for protection to his head from bursting 20 mm Oerlikon shells led him to remove the liner of his helmet and pull on the outer steel shell over his regulation leather flying helmet The effectiveness of this protection was emphasized by the fact that his pilot, wearing only a leather helmet, was struck in the head by the fragments of an Oerlikon shell which burst between them He immediately lost consciousness, developed a left hemiplegia, and a complete left homonymous hemianopsia While the copilot's helmet was punctured in several places by the high velocity fragments, it afforded complete protection from even a scalp laceration

It became obvious that members of an aircrew needed adequate protection from craniocerebral injuries However, any helmet designed for their use had to meet certain specifications

- 1 It had to be close fitting and comfortable so that it would simulate as closely as possible an ordinary leather flying helmet and be considered a personal possession which might gather "good luck," like a favorite, battered felt hat

- 2 It had to allow free and unrestricted movements of the head in all directions, and could not interfere in any way with the field of vision

- 3 It had to be light in weight and afford protection from the heat and cold

- 4 It had to afford protection, at least equal to that afforded by the regular issue steel helmet, against craniocerebral injuries produced by fragmenting Oerlikon shells and antiaircraft flak, or concussion due to direct, blunt trauma If these requirements could be met for aircrews the same type of helmet would serve for tank crews that used a fiber helmet which the soldier found unsatisfactory for protection, efficiency, or comfort

The percentage of wounds to the head, comparing its surface area to that of the body, is approximately 12 per cent It was found that the larger number of craniocerebral injuries in airmen resulted from the fragmentation of 20 mm Oerlikon shells, followed in turn by the larger pieces of antiaircraft flak, and concussion due to direct trauma When an Oerlikon shell bursts, it fragments into thousands of pieces which vary in weight from less than 1 mgm to 20 gm However, the largest number of "effective" Oerlikon shell fragments bursting in an area 5 feet in diameter and capable of causing incapacitation to the person exposed is 260 The majority of these 260 fragments weigh between 10 and 50 mgm and their velocity varies between 400 and 600 meters per second

Many materials were suggested and subjected to accurate ballistic and other tests It was finally

concluded that an acrylic resin, properly manufactured, offered the largest number of advantages for the purpose and most closely met the specifications for velocity resistance, tensile strength, impact resistance, hardness, specific gravity, inflammability, nonconduction of heat and cold, and tissue reaction. A model helmet was made by molding pieces of acrylic resin to conform to the frontal, temporal, occipital, and vertex portions of the skull covering them with leather, and lining them with chamois skin and fleece. Such a helmet allowed for complete movement of the head in all directions, provided complete protection over the frontal and occipital areas, and weighed 18 ounces, compared with the steel body of the regulation helmet which weighed 35.84 ounces. A commentary on the organization within the Army is that this type of helmet was field-tested and adopted for Marine and Navy flyers, but further work upon it by the Quartermaster Corps of the Army was prevented by a directive which forbade this corps to interest itself further in protective clothing of any description for the Army Air Corps.

Blast injuries. Investigation of the cerebral symptoms after blast injuries was carried on by Zuckermann and his associates for the Ministry of Home Security in Great Britain, where, of course, the greatest opportunity existed during the Battle of Britain. They found no evidence of cerebral lesions in experimental blast, and the cause of the clinical symptoms still remains in doubt. However, others did report hemorrhagic cerebral lesions in patients without any wounds of the head. Cairns believes that the possibility of cerebral fat emboli still remains in question, although in some cases fat was looked for in the brain lesions and not found.

Mechanics of craniocerebral injuries. A series of recent investigations has emphasized the facts that nerve tissue, blood, and cerebrospinal fluid have about the same density as water, that the brain substance does not change its size appreciably when subjected to hydrostatic pressure, and that the brain offers very little resistance to changes in shape as compared to the resistance it presents to changes in size. Obviously, the rigidity of the skull is enormous compared to that of the brain.

Deformation of the skull has been recorded electrically and is, as would be expected, most severe near the point of impact where there is compression distortion. Simultaneously on the opposite side, there is tensile deformation. Since the brain substance is extremely incompressible and yet easily altered in shape, its constituents

are pulled apart in proportion to the degree of sliding type of deformation.

Another mechanism acts to injure the brain; it is due to the changes in velocity of the head produced by the blow. Linear or rotational acceleration forces, or both, may be set up, and of these the latter are the most injurious. The small amount of motion allowed the brain in its closed box is possible only because of the to-and-fro movement of the cerebrospinal fluid. When the head is subjected to rotational acceleration forces, the brain lags behind and a type of shearing strain results. Denny-Brown and Russell found it difficult to produce concussion in animals if the head was prevented from moving when it was struck.

INTRACRANIAL ABSCESS

The influence which the antibiotics have had upon the result of the surgical treatment of intracranial abscess has been almost miraculous. There was a time not far distant, however, when this intracranial lesion was one of the most disappointing which beset the surgeon. The sterilization of the contents of the abscess, the safety with which one can wait until the abscess wall is well established, the avoidance of ventriculitis and meningitis, and, finally, the success which has attended removal of the abscess in its entirety, without the development of widespread encephalitis, constitute a real contribution to this field of surgery. Chorobski has recently reported upon removal of the abscess in its entirety in 26 cases.

SPINAL CORD INJURIES

The record attained in the treatment of patients with spinal cord injuries in World War I was not an enviable one and the methods of treatment of traumatic paraplegia were not improved a great deal by the experiences of that war. The contributions of Riddoch, Holmes, and Head to the physiology of the spinal cord, which resulted from their meticulous study of the relatively few patients who survived following injury to the spinal cord in World War I, are unequalled in clinical observation. In the succeeding years the majority of the patients were injured in industrial or traffic accidents, and the greater part of the injuries were of the closed fracture-dislocation type. A second opportunity for improvement in the methods of treatment of spinal cord injuries was at hand with the beginning of World War II and the tremendous number of wounds of the spinal cord from every conceivable cause. It is doubtful if careful and accurate clinical studies of the 2,000 odd traumatic paraplegic patients who are still alive after World War II were made during the time

they were being cared for in military hospitals. Such studies are now being undertaken in Veterans Administration hospitals where these patients are now under care.

It is unfortunate that many paraplegic patients misunderstood the assurances given them by the Army that over 80 per cent of them would walk. These tragic individuals have learned in these last few years the difference between ambulating and walking. They, quite naturally, had expected to walk in the manner to which they were accustomed before their injury and irrespective of the level of that injury. This overenthusiastic approach did more harm than good and led to ill advised actions by members of Congress and other well meaning laymen which made the paraplegic patient consider himself in a group set aside from other seriously wounded and permanently handicapped veterans. The problems of the care and treatment of patients with paraplegia must be thoughtfully carried out to a solution. There is no doubt but that the problems of these patients have been built up too strongly in the public mind. They have become the center of much interest, not all medical, which may eventually make their care even more difficult. The very word "paraplegic" is objectionable. It is frequently heard from the lips of patients and lay persons, singling out and stamping these patients as doomed with a special and completely hopeless disability. A less pointed, less specific term should be adopted. These patients are seriously and tragically injured persons and should be treated as such, but they should not be singled out for overindulgent publicity from those with other types of injury just as serious and, in many cases, more disabling.

Surgical treatment Even with the large experience gained from spinal cord injuries in World War II there is still no agreement upon a course of surgical procedure which should be carried out in the treatment of the patients immediately after injury. This should not be surprising. On the contrary, it is surprising that it should be expected that these injuries, which exhibit so many different symptoms, could be typed so strictly that any one particular group of therapeutic steps would be the correct one in all instances. The greatest unanimity of opinion, and undoubtedly the greatest contribution that has been made as a result of World War II experience, has centered on the rehabilitation of the patient. The high quality of the early care of the patients with spinal cord injuries in this war has kept them alive so that rehabilitation could be effected.

In the past, the term "spinal shock" has been used frequently and without critical meaning.

The term should be discarded because attempts to interpret it often have deprived the injured patient of the sorely needed help of a surgical procedure. Any patient with an injury of the spinal cord, with or without concomitant injury to other parts of his body, may suffer from a fall in blood pressure, a low body temperature, and a poor pulse and give evidence of poor peripheral circulation. Unfortunately, the term is interpreted by some to mean that the patient has a complete anatomical section of the spinal cord because he may be flaccid and without reflex responses of any type below the level of his injury. As a matter of fact, early in the phases of a spinal cord injury the differentiation between a complete anatomical and a complete physiological lesion cannot be made upon the basis of clinical symptoms. It has been said that plantar flexion of the great toes is usually the only reflex movement that can be elicited upon scratching of the sole of the foot during the first few weeks after a complete transverse lesion of the spinal cord, and that the appearance of a Babinski sign within the first 2 weeks after injury is evidence of the incompleteness of the lesion.

Most surgeons will agree that the patient should be recovered from the primary shock of his injury before treatment is begun, whatever may be indicated. Similarly, most surgeons are agreed that the final position of the patient with an injury to the thoracic or lumbar spine, with or without cord injury, and whether or not the patient is subjected to laminectomy when the cord has been injured, should be that of hyperextension. Fixation upon a special hyperextension bed with a reverse spring mechanism, or by means of rolled blankets under the mattress, and without a plaster cast, should be obtained. Plaster casts, so dear to the hearts of the orthopedic surgeons, create many problems of nursing care, contribute to the formation of decubiti and add to the general discomfort of the patient. Manipulation of the spinal column to reduce a fracture-dislocation is only mentioned to condemn the practice emphatically. Some form of skeletal traction is preferable in the care of cervical fracture-dislocations, and to the majority of neurological surgeons the use of skull tongs has proved the simplest, most effective, and safest method of obtaining traction. It has become standard practice to apply tong traction early in cases of fracture-dislocation of the cervical spine when there is no open wound and when there is no evidence of indriven bone spicules or other foreign bodies.

The greatest point of contention in the treatment of injuries of the spinal cord concerns the

problem of when, if ever, laminectomy is to be performed. The Queckenstedt test offers the most reliable method of demonstrating the presence or absence of a block in the subarachnoid space, whether it be due to edema of the injured cord or to pressure upon the cord by dislocation of the vertebrae. It offers a method of following the release of that block by subsidence of the edema or by closed methods of re-establishing the free circulation of the cerebrospinal fluid. Or, it establishes the indication that a laminectomy must be performed to relieve the block. The surgeon cannot repair the injured spinal cord, he can only relieve compression and provide every opportunity for the spinal cord to regain its function. The differentiation between complete anatomical and physiological interruption cannot be made in the period which is important to the patient's future. Therefore, the Queckenstedt test is important in defining the responsibilities of the surgeon.

A large number of patients with spinal cord injuries who have had a subarachnoid space block from the time of their injury have been observed in a Veterans Administration hospital. In the majority of these cases, the continuity of the spinal cord had not been interrupted anatomically. One can only surmise what the course of the patient might have been had the subarachnoid space block been followed up persistently and the compression relieved early after the injury. If it was not relieved by closed methods of traction and hyperextension then certainly a laminectomy should have been performed to have given the patient every opportunity to recover part or all of his cord function.

Certainly, decompressive laminectomy weeks and months after injury rarely offers any benefit when evidence of a complete transverse lesion has persisted. However, this is not true, even in late operations, when the lesion has been incomplete and not progressive. Early or late, operation has much more to offer in injuries of the cauda equina than it does in injuries of the spinal cord. When the injury is in the cervical cord, skeletal traction should always be tried first. Early and premature cervical laminectomy, within the first few hours or days, is bad surgical judgment and is the one instance in which surgery contributes to the already poor prognosis of the case.

The open wounds of warfare require the usual meticulous débridement that all such wounds require. It was common practice in World War II to remove all bone fragments and make a clean toilet of the wound without opening the dura mater in the potentially infected field. Indriven spicules of bone and foreign bodies, if accessible,

were removed. Dural rents were closed either by suture, if possible, or by the application of living fascial grafts in order to stop the cerebrospinal fluid leak. In the fresh open wound only the bone that was actually damaged or in danger of not remaining viable was removed. The excellent healing and frequent return of function, particularly in incomplete lesions, which resulted from such treatment has provided fresh hope in the care of these patients. The aid of systemic chemotherapy has been as great a boon in this field of neurological surgery as it proved to be in craniocerebral open injuries.

Rehabilitation. The time finally arrives in many injuries of the spinal cord, in particular those of the cervical and thoracic segments, when all active treatment for the injury itself is futile. The patient must be prepared for existence as a bed patient, a wheelchair patient, or as an ambulant patient with the need for crutches, braces, or walker, this depending entirely upon the level of his lesion. World War II gave a tremendous impetus to the re-education of the patient with a spinal cord injury. The programs for the rehabilitation of these patients in certain Veterans Administration hospitals are being carried out on a broad and detailed scale, but they are no different, actually, from those which have long been advocated by many neurological surgeons in the care of patients with similar injuries received in civilian life. Carefully supervised recreation, physical therapy, occupational therapy, and study in trade schools are all parts of a general program to improve the morale of the patient, to help him readjust himself to a happy and, if possible, useful existence, and to give him the maximum chance for physical recovery. The great force promoting such a program has been, happily enough, the United States Government, as reflected through the care given these patients by the many civilian doctors who have given of their time and abilities to the Veterans Administration hospitals and the hospitals of the Army and Navy.

Late care of the patient. The primary responsibility of the care of the patient with a spinal cord injury should be that of the neurologist, with the aid of the neurological surgeon, the urologist, the orthopedic, general, and plastic surgeons, and particularly of the internist who can consult in problems of general medical care and nutrition which constantly arise. When the patient is thus handled, he requires no more special psychiatric care than any other type of patient with a chronic illness.

The special difficulties of nursing care are multiple and a large personnel is needed to give pr-

tients with spinal cord injuries a consistently maintained high level of attention. The daily nursing problems which attend the care of the bowels, bladder, decubiti, nutrition, cleanliness of the skin, and morale require a persistent attitude of optimism on the part of all the ward personnel. This cannot be obtained by the written order in the book, it must be implemented by the supervision of competent, interested doctors and nurses, particularly the latter whom the patient sees more than any one other person. A hopeful, friendly, interested approach has proved to be a great factor for good.

Nutrition The value of the correct blood protein level and the albumin-globulin ratio has been demonstrated repeatedly in the care of these patients. The diet must be carefully supervised to provide a high protein intake and an average caloric supply of about 2,800 calories a day. It is not primarily the purpose to have the patient gain weight, although well fat-padded weight-bearing points are less likely to develop decubitus ulcers. It is the latter which seriously deplete the plasma proteins. A high vitamin diet is also desirable, and for the purposes of improving the status of the bladder a generous fluid intake should be urged.

Decubitus ulcers Every meticulous detail of nursing care must be insisted upon to avoid rather than to heal the decubitus ulcer. Weight bearing points on the body must be rested frequently by turning the patient, and by massaging and drying the skin. Sheets must be clean and smooth. The skin must be bathed frequently and kept dry and free from feces, urine, and perspiration. Attention to the avoidance of decubitus ulcers must begin within the hour after injury and can never, for the rest of the patient's existence, be relaxed at any time. There is no questioning the fact that delayed and inadequate nursing care during the first few days after injury, in the theater of operations, was the main source of bed sores. It was for this reason, among others, that doctors insisted upon evacuation priority for these patients, oftentimes unsuccessfully against the obstinate obstruction tactics of laymen in other echelons who were preoccupied in the transportation of matériel and personnel designed to make their own existences more comfortable.

Once a decubitus ulcer has developed, it should be treated with all of the meticulous care necessary to prevent the introduction of further infection, as sloughs appear they should be carefully removed, the base of the ulcer which consists of granulation tissue should be kept fresh and clean. The use of ointments, no matter how brightly colored, upon the ulcer does not conform to the

sound surgical principles established for the successful treatment of this kind of a wound. The purpose is to close the wound as quickly as possible after the disappearance of infection. This can be accomplished most quickly by excision and closure in the small ulcers, but in others free grafts or rotation flaps must be used. Eventually some ulcers will epithelize but the healing process is a slow and tedious one and the patient is handicapped in his rehabilitation by the long period required.

Development of automatic micturition The establishment of efficient urinary function is one of the primary goals in the care of the patient with an injury of the spinal cord. It avails little to rehabilitate the patient successfully in various other spheres if eventually he does not have adequate control of his urine, for in such a chronically disabled patient the inability to void with some means of control will alone prevent his return to a socially acceptable state. Furthermore, proper urinary function, in so far as it can be developed, is important for the preservation of life itself.

It has been accepted as fact that the appalling death rate among the wounded of World War I who suffered spinal cord injuries was due to urinary sepsis probably induced by early repeated manual catheterization. It would seem that in World War II, the method of choice in the care of the bladder was early suprapubic drainage with a large tube placed well above the symphysis pubis. Later when the patient reached adequate hospital facilities, the tube was removed and replaced with a permanent indwelling catheter. It has been established as a principle by testimonials and not by proved facts that a suprapubic tube was necessary "for purposes of transportation." It was the experience of more than one neurological surgeon to receive the patient at a base hospital with urine oozing out around a plugged-up suprapubic tube (which promoted the formation of decubitus ulcers), with a necrotic fistula, or, on occasion, with the neglected tube rotted off and lying free in a mass of calculus in the bladder. The British have described a "trocar" method of performing the suprapubic cystostomy with insertion of the tube immediately above the symphysis, but observation of several British wounded with spinal cord injuries showed that this method of management was not proof against the thoughtless or careless doctor.

Tidal drainage, generally popular in America, requires attention from the doctor, nurse, and patient. It is not a simple, self-regulating mechanism as many assume, but it affords a means of continuous cystometric study, it is a means of

Of these 471 patients, 126 complained of pain so severe as to require the consideration of active steps for its relief. In 8 of these patients the cervical spinal cord was injured, in 73, the thoracic portion of the cord, and in 45, the lumbar cord and cauda equina. In general, the pain experienced by the patients could be classified as (1) root pain, (2) burning, tingling, and poorly localized pain, and (3) visceral pain, characterized by its cramping, diffuse, and vague character.

The onset of root pain usually occurred within a few days to a few weeks from the time of the injury. Only 1 of the patients with an injury of the cervical spinal cord complained of this type of pain. Twenty-eight of the 73 patients with thoracic spinal cord injuries and 38 of the 45 with lumbar cord and cauda equina injuries suffered similar pain, which was unrelieved by medication but in many cases gradually abated in severity, although it never disappeared entirely without surgical attempts directed toward its relief.

Every one of the 126 patients complained of continuous, burning, tingling pain which was diffuse, was never localized narrowly, and almost never corresponded to the peripheral distribution of a dorsal root. Segments of the body below the level of the spinal cord lesion with complete loss of sensation to the usual sensory stimuli were involved, such as both feet or both legs below the knee. The most common description was that of burning, "shooting like electricity," "tingling like that following frostbite," and a "feeling like pins and needles." Many patients described this type of pain as being more severe with the onset of cold and damp weather, in many the pain was increased when they became excited or depressed, in others it was increased by the light contact of a finger or the touch of a wisp of cotton. Movement of the body, jarring of the bed, fatigue, attempts to concentrate upon moving the toes, and smoking were all described as factors in making the pain worse.

The onset of this pain occurred immediately after injury to several months later. Holmes stated that in the cases he observed it reached its maximum upon the second or third day after its onset and began to subside toward the end of the second or third week. He knew of no patient in whom this type of pain persisted unabated beyond a month or so after injury. In general, the patients also described this burning pain as gradually increasing in severity for a time after its onset and then becoming less severe, but in many instances the pain has persisted for 4 years and in all of them constitutes a major complaint for

which they intermittently seek relief. There is no question that personality is a definite dominating factor in this type of pain. The nature of the pain assumes different attributes depending upon many emotional factors. The hot, burning pain would be replaced at times by severe crushing pressure, by sensations of viselike pinching or of streams of fire running down the legs into the feet and out of the toes, or by a pain such as produced by the pressure of a knife being buried in the tissue, twisted around rapidly, and finally withdrawn all at the same time. Many of the less well adjusted patients related this pain to the existing or healed bed sores from which the burning seemed to originate. In many respects, this pain resembles that complained of in phantom limbs, particularly with regard to its peripheral projection.

The type of pain that is classed as visceral pain must be sharply differentiated from the root pains and the diffuse, burning, unlocalizable, painful sensations just described. It is a sensation of fullness in the abdomen related directly to distention of the urinary bladder, with cramping, vague, diffuse, periumbilical, and hypogastric pains which occur when the patients receive enemas and the fluid is injected rather high, and the bowel is distended. In these patients the painful sensations continued until the bowel or bladder was completely evacuated. Many of the patients had a feeling of nausea, sudden profuse sweating, flushing of the face, headaches, and priapic erections. In fact, in many patients a headache and flushing of the face and neck constituted the only warning that the bladder was full and was about to evacuate automatically. These visceral sensations of pain occurred in more than 80 per cent of all the patients regardless of the level of the spinal cord injury, but they were presented by the patient as complaints for which he wished relief in only 6 cases of thoracic cord lesions.

Cordotomies were performed on 18 patients for the relief of pain, 23 operations were performed, and 1 patient had 3 operations. Only 1 patient received lasting relief from the burning diffuse pain following cordotomy, 2 received relief for 1 and 2 weeks, respectively, after which the pain returned exactly as it was before operation. Four patients received complete relief from severe root pains, and 13 had no relief from root pains following the operation. These operations were performed in Army general hospitals and in the majority of instances by inexperienced and unqualified neurological surgeons. In 6 of the patients who had lesions of the cauda equina and

who had no relief from the cordotomy, the sensory level and motor loss were at a higher dermatome level following the operative procedure, with a greater loss of automatic bladder function than had previously existed

In 2 patients with cauda equina lesions who had both root pains and diffuse, burning pain in their legs, paravertebral alcohol injections of the lumbar sympathetic trunk had been made. In 1, temporary relief of the root pains for 3 days was obtained, but in neither patient was there relief from the burning pain

Thirty patients who complained bitterly of burning, diffuse pain were given intravenous injections of tetrathyl ammonium chloride to determine what effect this strong vasodilator drug might have upon their pain. In all of them, coldness of the lips, dizziness, slight nausea, and weakness occurred, but there was not a uniform striking drop in the systemic blood pressure and in none of them was there any significant relief from the pain

The clinical course of each of these patients was characterized by the administration of all types of sedatives, and in some it has been necessary to relieve the patient of narcotic addiction. There was no drug or combination of drugs which afforded them any more relief from the burning pain than did an occasional capsule of aspirin, phenacetin, and caffeine. It must be emphasized that more than 90 per cent of the total number of patients complained at some time following their injury of the diffuse, burning pains that have been described but, with the exception of this series of 126 patients, the pain either disappeared entirely and without any specific treatment, or the patient became completely adjusted to its presence and was aware of it only after an emotional upset or for some minutes immediately before he fell asleep

Reflex activity The loose employment of the terms, "mass reflex," "spasm," "paraplegia in extension," "paraplegia in flexion," and "spinal shock" leads to confusion in any discussion of one of the most serious problems which must be faced in the care of the patient with a spinal cord injury. These conditions are all manifestations of the same general state of altered spinal reflex activity. It is difficult, probably unnecessary, and not even desirable, to categorize all the variants of these alterations. An understanding of the nature and cause of bizarre reflex activity in man after spinal cord injury must come from a study of man

The large number of patients with spinal cord lesions who have survived long periods following

their injuries, because of the excellent care they received in comparison with World War I, has made it possible to observe and study the reflex activities which are present and when they made their onset, also their character and their relation to the general physical state of the patient.¹ Abnormal reflex activity, appearing early or late, may manifest itself in the responses to plantar or other superficial stimulation, to muscle stretching, to genital stimulation, and to the stimulation of either the bladder or bowel. The vasomotor, pilomotor, and sudomotor responses which accompany the various striated muscle contractions may be entirely erratic. Certainly, the patterns of reflex responses in these individuals are rarely repeated often enough to make them reliable for diagnostic or prognostic use

It is commonly stated that after a severe injury to the spinal cord the condition of "spinal shock" ensues (in man for 3 or 4 weeks), during which time reflex activity is absent. The term "spinal shock" is an unfortunate one. After the first few hours are past, the truly shocking effects of the trauma have worn off, and the patient has had the customary supportive care (including surgery if that is necessary), the patient is usually comfortable, shows satisfactory blood pressure, pulse, respiration, and temperature readings, and is normally active above the level of the lesion. The exception, of course, is the midcervical or high cervical lesion which so commonly results in early death. It is hardly tenable, furthermore, that shock can be said to persist for weeks at a time with the patient in good condition save for his paralysis. This interval should be designated as one of *decreased reflex activity*. However, all reflex activity is rarely gone. In fact, the genital reflexes (active ischiocavernosus and bulbocavernosus muscle reflexes with erection) may appear immediately to be persistent over a long period of time. Erections occurring immediately have been noted in patients with transected or incompletely crushed cords, both in the cervical and thoracic regions, and this reflex has been seen to remain active and easily provoked for as long as 4 years after injury. Indeed it is through stimulation of the external genitalia (but not with nocuous stimuli), the perineal skin, and the inner surfaces of the thighs that one may first note the onset of the second stage, or the state of *heightened reflex activity*.

¹Four hundred ninety patients have been observed and studied in civilian practice in Army general hospitals and in a Veterans Administration facility. Some of the patients were taken care of immediately after their injury and followed up through their entire course; others were taken care of immediately and later followed up in Veterans Administration hospitals. Still others were seen for the first time in the latter hospitals as long as 5 years after their original injury was received.

With the beginning of this second phase, there appear the early visceral and vasomotor reflex changes, and flexion, extension, or adduction of parts of the lower extremities. After the first day or two, there is frequently, although not characteristically, an almost normal appearing flexor movement of the toes on plantar stimulation. During this period there is retention of urine and catheter care is necessary. The bowels require enemas, but ordinarily automaticity of the bowels, if it develops at all, will begin at an earlier date than similar function of the bladder. Knee and ankle jerks are absent during the early days after injury. Bladder irrigation and enemas seldom cause flushing, sweating, headache, or "crampiness" in the abdomen before the fourth week has passed. The skin below the level of the lesion becomes quite dry, pale, and lifeless, especially on the feet and ankles, and tissue turgor is poor. It is during these first few weeks when vasomotor stability is lost in the skin that bed sores are most likely to develop.

Except for the ever present specter of decubitus ulcers, the patient is usually a nursing problem of ordinary degree during the period of depressed reflex activity, taking into account the special attentions to the bladder, the skin, and the state of nutrition. Neurological recovery, if it is to occur, will show some signs fairly early, and the persistence of depressed reflex activity, with or without any plantar responses, usually means that a complete physiological, if not anatomical, lesion exists. Sherrington discussed the period of "shock" in a few paragraphs, hardly improved upon to this date, when he stated, "Spinal shock appears to take effect in the aboral direction only. Section behind the brachial enlargement disturbs little if at all the reactions of the fore limb, although the number of headward running channels of conduction ruptured by such a section is enormous."

On the aboral side of the transection depression is profound. The view of Goltz and his school that 'spinal shock' is a longstanding inhibition due to irritation by trauma is not, I think, really tenable. Were the mere irritative actions of the trauma the cause, it is not easy to see why the nervous centers near the trauma should not be depressed on either side of, for instance, a spinal transection, headward as well as backward.

There remains the further question as to whether spinal 'shock' is a phenomenon of inhibition. The condition of the spinal reflex-arcs in spinal shock appears to resemble a general fatigue rather than an inhibition. It renders difficult and uncertain the process of conduction along the reflex-arc as judged by the discharge from the ter-

minal neurone. This suggests a loosening of nexus between the links of the neurone-chain composing the arc, a defect of transmission at the synapse. I think, therefore, that spinal shock is neither due to irritation by trauma, nor in the main a phenomenon of inhibition. The rupture of certain aborally conducting paths appears to induce it."

The genital reflexes and the occasional flexion of the toes on plantar stimulation, particularly with nocuous stimuli, occurred in patients as early and as actively regardless of whether or not the cord was completely transected or severely crushed, or whether any other form of trauma was the cause of interruption of normal physiological function. Furthermore, the profoundness of the absence of other forms of reflex activity will be found to be the same when there is complete physiological (with or without complete anatomical) interruption of the cord. The problem which remains unanswered, therefore, is the cause of this sudden and persistent state of depressed reflex activity, increasingly profound as one ascends the phylogenetic scale.

Riddoch apparently also accepted the theory that separation of the effector mechanism from cerebral control was the cause of the altered post-traumatic reflexes. It seems to us, however, that if the conditions of altered reflex activity were due solely to loss of cerebral direction because of neuronal interruption, the state of change should remain the same from the time of injury, since the interruption, once effected, is final. It would seem more logical that at least one factor in the appearance of these reflex states would be a change, in the intact and adequately vascularized segment of cord and its peripheral nerve and end organs below the level of the lesion, of a histological and chemical nature. If that were true, it is possible that during the state of depressed reflex activity the various parts of the reflex-arc, including the myoneuronal junctions, are inactive in a period of re-orientation and reorganization of function and in a state of autonomous function of a primitive nature. In this state of autonomy, however, the organs most affected, the muscles, do not atrophy apparently because of the viable cord, even though connection with the upper motor neuron is lost.

It is unfortunate that in neither animals nor man can the complete anatomical and complete physiological lesion be differentiated early. By far the greater number of patients with early complete loss of all neurological function but without gross anatomical section of the cord remain as profoundly and persistently lacking in return of function as do those known to have had the cord actually severed. There is little difference in the

deep tendon reflexes, plantar responses, muscle spasms, and genital and viscerovisceral reactions in patients with clean anatomical cord section and in those with crush, preservation of continuity of the cord, but permanent failure of neurological recovery. Gross anatomical section assures the physiologically complete lesion, but a severely contused cord undergoes such softening, with later gliosis, that it, too, is in a microscopic sense anatomically severed.

Be the injury cervical or thoracic, or open or closed, with a complete lesion of the cord as indicated either by surgical verification or by the long persistent failure of recovery, the severity of the heightened reflexes varies from patient to patient. There are those patients who never at any time develop anything more than the mildest degree of spasm, while others early and rapidly progress to such a condition of hyperactive reflexes that the persistent deformity calls for specific medical or surgical care. It has been observed that the early care of the patient has much to do with his later period of heightened reflex activity. When the proper surgical care has been given early, and all supportive measures, such as early ambulation of the patient, physical therapy, proper care of the bladder, the avoidance of decubiti, and other sources of sepsis and general debilitation have been attained, patients have been spared later excessive reflex activity and all the attendant ills. The greatest single factor that is under the control of those who care for such patients in securing a smooth convalescent course is the avoidance of sepsis, especially that which arises from the urinary bladder. Spasm has been greatest in the patients injured in a theater of war, whose early care was often incomplete or in whom a state of sepsis and malnutrition was established. Invariably, patients ideally cared for in civilian life have not been found to develop such severe and disabling reflex activity. The incomplete lesion, as would be expected, produces less severe spasm according to the degree of neurological loss.

The *date of onset* of the phase of heightened reflex activity is not affected by the severity of the lesion, its completeness, or whether it is in a patient with a closed or open wound of the cord. Many patients have been observed with incomplete lesions, whether verified surgically or by the results of neurological examination and continued observation, who developed increased reflex activity as soon as patients with complete lesions. However, in many patients with incomplete lesions recovery will manifest itself within a few hours or days, and with the appearance of neurological recovery the state of "shock" must be said

to have terminated. Few incomplete lesions show symmetrical bilateral loss, and therefore the resultant state of hyperactive reflexes is seldom the same in the lower extremities. The patient with a completely severed or a hopelessly crushed cord will usually develop the state of heightened reflex activity no sooner or later than the patient with the contused cord which never shows any neurological function later. The date of surgical treatment, if given and regardless of its type, has not been found to affect the date of onset of the heightened reflexes. Patients have been seen with essentially an immediate onset of hyperactive, bizarre reflexes who never exhibited a period of decreased reflex activity for more than a few hours. The date of onset of heightened reflexes varies widely. It occurred in 1 patient with a complete lesion of the cord at the sixth cervical segment at the end of a full year, and in a patient with a complete lesion at the eighth thoracic segment at the end of 23 months. The average time of onset of the state of heightened reflexes was 15 months in the group of cervical injuries, and 25 months in the group of thoracic injuries. Small signs of beginning reflex activity, such as the upgoing great toe or beginning flexion withdrawal of the limb may be manifest in a feeble manner for several days, so that the transition from the state of depressed to heightened reflexes is not an abrupt one.

Many different factors affect the *nature of the reflex response*. In patients known to have partial loss of cord function the reflex patterns are most commonly extensor in type and at all times are less violent in nature. The stimulus applied, however, need be no stronger to produce a response in such a patient than in a patient with a complete lesion. In complete anatomical severance of the cord or in those patients with severe crush and persistent lack of neurological change, the reflex pattern is usually one of flexion, or flexion with adduction. Variations are many and even in a patient with complete transection of the cord well above the lower end of the cord, the response is seldom of exactly the same pattern or sequence in the two lower extremities. In its most violent form the abdominal muscles contract (when the lesion is sufficiently high), the thighs adduct, and the foot rises dorsalward, all together with flexion at the knees and hips. Several patients have developed, at some time in their hospitalization, contractions severe enough to dislocate the femur on one or both sides. One patient with an incomplete lesion at the tenth thoracic segment had extensor spasm when up walking in braces (effect of posture), but flexion-adduction of a severe degree when lying in bed and making no voluntary effort.

Ordinarily, the stronger the stimulus the more prompt and violent will be the response. Furthermore, repetitive small stimuli may, in summation, become great enough to evoke a response, a fact known to all students in the physiology laboratory. The point of stimulation is an important factor, for while on theoretical grounds the reflex appears segmentally according to the level of the stimulation, actually it is not quite that accurate. Midline stimulation, as on the skin of the pubis, genitalia, or perineum, will customarily evoke a bilateral flexor-adductor response of the lower extremities, at least as low as the knees, but plantar stimulation on one side almost invariably produces a more prompt and violent reaction on the ipsilateral side. Painful stimuli will more promptly evoke reflex activity of the lower extremity than any other form of stimulation.

Riddoch frequently mentioned the fact that many stimuli of an innocuous nature produce penile erection, often with the ejaculation of semen. It has been observed, in confirmation, that priapism may appear immediately after injury, particularly when the lesion lies above the sixth thoracic segment, and may persist throughout the period of "shock" and for months and years afterward, without decrease in the excitability of the ischiocavernosus and bulbocavernosus muscles. In the early days following injury the priapism comes and goes apparently independent of any applied stimulus, as if it were a part of the general state of vasomotor instability. Later, during the stage of heightened reflex activity, washing or stroking of the lower extremities, passing a catheter, bathing the genitalia, or turning the patient upon his abdomen may bring on the erection. In the patient with easily evoked flexor responses, a strong pricking of the soles may produce what Riddoch called the "coitus reflex" with contraction of the abdominal muscles, extension of the lower extremities, and erection of the penis. It has been observed that characteristically during this reflexly induced erection the cremaster muscles contract with elevation of the testicles and the muscles of the bulb may be felt to contract. However, the glans and corpus spongiosum never have been found to become as turgid or to persist in an erect condition so long as do the corpora cavernosa, and the penis seems more ballooned up by a sudden influx of blood rather than actually erect in the usual sense. The emission of semen has never been observed and upon extensive questioning it is the exceptional patient who has seen that phenomenon. Occasionally semenlike material in small quantity may be seen at the meatus around the catheter, or the patient may report he has seen

a quantity of white ropery material in the freshly passed urine. The few patients admitting masturbation report the failure of any seminal emission. Nocuous stimuli to the erect penis produces a prompt return of the organ to the flaccid state.

It is commonly stated that perspiration does not occur below the level of a complete lesion. On the contrary, with lesions as high as the fourth thoracic segment, such profuse, dripping perspiration over the buttocks and thighs as to be a threat to the development of macerated skin and decubiti has been seen. These same facts were described in detail by Head and Riddoch. It has been observed, especially in the upper thoracic lesions, that a full bladder, just before its automatic evacuation, or a bowel distended by an enema, may produce an extensive flush of the body above the lesion, headache, perhaps nausea, "gooseflesh" on the skin of the lower extremities, and, finally, on evacuation, a return to normal color of the skin of the face, neck, and arms, with the sudden appearance of beads of sweat over the thighs and trunk. Rarely with a lesion at any level have the ankles or feet shown more than a minimal amount of perspiration. In many patients these same visceral responses may follow strong stimuli that produce flexor activity, such as pricking of the soles of the feet. After the first 8 or 10 days, during which the bowels are usually constipated, manipulations of the lower extremities, bathing the patient, or changing his position may result in the sudden evacuation of the bowels. As the months wear on, however, the bowels develop a tendency to either spontaneous evacuation or evacuation after enemas or digital stimulation of the rectum, but, in any case, with a decreasing tendency to take part in the generally heightened reflexes. The visceral reflexes tire easily, more readily than those of the striated muscles, but they are equally sensitive in the resting patient. Given a patient who has been lying quietly in bed without even the stimulation of covers touching his exposed skin, the slightest touch on the thigh or groin may cause a spurt of urine, whereas a series of such minimal stimuli are usually necessary to evoke a notable response of the muscles of the lower extremities.

Every one of 372 patients with spinal cord injury had, during some period of his record, some degree of spasm in the lower extremities following the first few days or weeks of decreased reflex activity. By no means was the spasm of such degree to cause the patient concern or require treatment in all of the patients.

In the vast majority of these patients adequate nursing care, well directed physical therapy, and the maintenance of the general physical well being

of the patient (especially by the avoidance of a septic bladder and bed sores) have kept the patients comfortable and allowed them to be sufficiently mobile to permit some mechanical aid to ambulation, such as a wheel chair, crutches, or braces.

The treatment of the patients whose condition demanded relief of the spasm has been either medical or surgical, or, in some instances, both. In general, the use of the common sedatives, such as bromides, has not affected the hyperactive reflexes. Curare in its various forms has been used on a considerable number of patients but as yet a prolonged effect and the avoidance of undesirable side effects have not been attained. Posterior rhizotomy, as well as the intrathecal injection of alcohol, has been used in isolated instances without effect. In the patients treated by posterior rhizotomy, no untoward effects on the skin of the affected segments have been noticed. Anterior rhizotomy as high as the tenth thoracic segment, inclusive, has been uniformly successful when applied over a sufficiently great enough number of segments, but the operation should be studiously avoided until it has been established beyond all doubt in the patient's mind that the lesion is complete. It is not always easy to isolate the anterior from the posterior roots at operation, nor is it always a simple matter accurately to identify the segments. This is true especially when the injury is at the spinal levels of the eleventh or twelfth thoracic, or the first lumbar segment.

Scarff and Pool have proposed the theory that the so-called mass reflexes and severe muscle spasms are influenced by scar tissue at the site of the lesion on the end of the distal cord segment. They believe that this cicatrix heightens the irritability of the isolated segment of cord, and that removal of the cicatrix, excision of all local degenerated tissue, and surgical section of the dorsal columns in the upper portion of the lower cord segment helps to allay or completely remove this condition. In 2 patients the scarred proximal and distal ends of the severed cord were freshly resected with the local removal of all irritating factors, such as abnormal vascular ingrowths, bone fragments, ligamentous cicatrix, and callus, but without prolonged or noticeable effect.

Some patients who suffered predominately from adductor spasm, and in whom the tendency for the lower extremities to cross has been a real impediment to their otherwise possible ambulation, have had immediate relief with improvement in their use of canes, crutches, or braces following the bilateral section of the obturator nerve, as approached through the lateral reaches of the space

of Retzius. Walking is not interfered with by this procedure, which has been performed in 22 patients. There is a smaller group of patients who, after months of deformity due to severe flexor-adductor spasm, are not relieved by anterior or posterior rhizotomy because of tendon contractions. These patients should be treated by tenotomy at the involved joints.

The very facts that certain patients develop extremely little "spasm," that some develop spasm very early and others very late, that some show extensor and other flexor responses with the same type of lesion, that the viscerovisceral reflexes are very marked in some patients, and that in some patients the spasm may spontaneously become greatly abated, as well as the fact that in the majority of patients sepsis definitely increases the severity of spasm, indicate that the adaptability of the isolated cord and its attached peripheral mechanisms to its new independence varies in patient to patient, and that this adaptability, as indicated in the variety of responses, is a matter of intrinsic change, anatomical or chemical, or both, within the various parts of the arc. It is toward a knowledge of these changes that our attentions should be directed, rather than solely to the observation and recording of the dramatic neurological changes demonstrated by physical examination.

RUPTURED NUCLEUS PULPOSUS

Some orthopedic surgeons still deny vehemently that there is such a pathological lesion as rupture of the nucleus pulposus through the annulus fibrosis with impingement upon and irritation of the nerve root. There are also those surgeons who believe that every pain in the back which radiates down the leg is due to such a lesion and, in fact, attribute these symptoms to "concealed discs." As is usually the case the truth lies in the middle ground.

In the European Theater of Operations of the United States Army, the policy was adopted that a patient with severe back distress and radiation of pain down an extremity along the course of the sciatic nerve should be treated conservatively by bed rest and other measures directed by the bone and joint surgeons. If these failed to give him relief and if he showed a postural defect, spasm of the sacrospinalis muscles, impairment of the active and passive straight leg raising movement, subjective and objective sensory disturbances in the distribution of the affected root, absence of the Achilles reflex, and a positive defect upon myelography, an operation for the removal of a ruptured nucleus pulposus was to be performed. It

was decided to keep separate the indications for removal of a ruptured nucleus pulposus and those for fusion of the lumbosacral spinal column. This policy has been found to be a very satisfactory one at a Veterans Administration hospital and in private civilian practice.

The results of these operations in military practice were on the whole quite unsatisfactory, but there were many complicating factors which influenced the result. If, after this operation, intensive and persistent physical rehabilitation exercises designed to strengthen the back muscles are insisted upon and carried out faithfully by the patient, the results will prove excellent as judged on the basis of a successful return to the former social and economic position. Removal of a ruptured nucleus pulposus will cure sciatic pain, but it will not cure a spinal column which needs a fusion operation.

PERIPHERAL NERVE INJURIES

The most significant advances in our knowledge of peripheral nerve injuries during World War I were made in the fields of diagnosis and physiology. There were a considerable number of British neurologists, physiologists, and surgeons, but only a few Americans, who made valuable contributions.

Unfortunately, the records of the studies made and the operations performed upon the patients with such injuries in the U. S. Army were completely lost, as far as any organized effort to follow the results was concerned. It was a bitter disappointment to the American neurologists and surgeons interested in peripheral nerve injuries and their British colleagues when the centers established immediately after the war for continued study of these patients failed to attain their objectives.

An effort was made in World War II to avoid the repetition of such wasted opportunities. A peripheral nerve registry was established by the Surgeon General's office and now, following the war, the Veterans Administration has allocated funds for follow-up examinations and studies upon the patients. However, a completely organized and well directed plan for accomplishing the best possible care of the patient and, at the same time, obtaining data which would answer many of the challenging questions that existed was never properly formulated and effected from the beginning. Certainly, anyone who had the opportunity of seeing the co-ordinated efforts in the care of peripheral nerve injuries at the Wingfield-Morris Hospital at Oxford, under Seddon, cannot have a great deal of hope for what may eventually come from our

belated, complicated, confused, and incomplete efforts.

Early in the course of the War, a great amount of energy and time was wasted by many of the younger group of neurological surgeons in proving to themselves that the work of Huber and his associates upon peripheral nerve problems during World War I was correct. There was a considerable preoccupation with mechanical matters, such as wrapping tantalum foil around a suture line, which effectively blocked its vascularization, using metallic tension sutures through the trunk of a nerve so that separation of the nerve ends might be followed roentgenographically, and attempting to find a suture material superior to fine silk. While some few operations performed made use of nerve grafts, the results were recorded long before one could possibly hope for regeneration through the transplant to occur and the use of homogenous grafts was damned. Yet, the answer to this question must come from the human being because in experimental animals microscopic proof of recovery with function by means of homogenous grafts has been obtained. The opportunity was presented in the Army general hospitals which were both amputation and neurosurgical centers. Fresh homogenous grafts could be obtained and immediately transplanted into patients with continuity defects which could be bridged in no other way. Granting that the grafts might fail, the patient had nothing to lose and everything to gain. So, we must continue to gather material slowly and laboriously from civilian cases in which transplants may be indicated, and they multiply slowly. The few cases in civilian life in which fresh homogenous nerve grafts have been employed have proved that they do not disappear by lysis, and in several instances the electrodiagnostic and clinical symptoms of regeneration are sufficiently encouraging to demand a careful assessment of the problem in the human being on a statistically significant number of patients.

A considerable amount of experimental research on peripheral nerve problems was planned and implemented through the Office of Scientific Research and Development and the National Research Council during World War II. Tarlov's work upon the use of plasma glue for the union of nerve ends which could be approximated without tension, the effect of the sulfonamides locally on nerve regeneration, the traumatic degeneration produced by the concussive effect of gunshot wounds which did not sever the nerve trunk (different as it is from Wallerian degeneration), the demonstration of new staining methods (other than the old accepted silver stains) of the

different patterns of nerve regeneration in end-to-end sutures and autogenous and homogenous grafts, and the electrodiagnostic and electromyographic methods elaborated for the study of denervated and reinnervated muscles were among these projects

Following animal experiments and studies carried out upon patients in an Army general hospital, Pollock and his associates emphasized the fact that faradic stimulation is effective throughout degeneration, denervation, and regeneration, provided that sufficient amperage is employed. The changes of response to galvanic stimulation of "infinite time" which characterize the complete reaction of degeneration are (1) hyperirritability of the muscle to galvanic stimuli, (2) sluggishness of the relaxation of the contraction wave, (3) lessening of the ratio between the amperage necessary to produce tetanus and the rheobasis to almost unity, and (4) increase of the efficacy of the anodal closing stimulus to equality with the cathodal closing stimulus. These workers also stated that the unequivocal signs of recovery are (1) a sudden increase in the rheobasis, (2) an increase of the ratio between the amperage necessary to produce tetanus and the rheobasis, and (3) an increase in the efficacy of the cathodal closing stimulus as compared with the anodal closing stimulus. A very high ratio or a very high threshold amperage is indicative of regeneration, and these electrical signs of recovery antedate the recovery of motion and sensation by many weeks.

The practical application of these electrodiagnostic methods can hardly be overemphasized. When a sufficient time after injury has elapsed to permit the development of the state of denervation and the characteristics of denervation are not found by electrodiagnosis, the nerve is spontaneously recovering and should not be operated upon. If, after a severed nerve is sutured, the characteristics of the denervated state are not found, it may be assumed with certainty that recovery is taking place. When a sufficient time has elapsed following nerve injury for regeneration to have occurred and the characteristics of denervation are found, then the nerve must be operated upon.

The question of how nerve fibers regenerate after division has been the subject of innumerable contributions beginning with Howell and Huber in 1892 and Ranson in 1912. The use of the silver staining technique precluded a simultaneous study of the nerve fibers, endoneurium, the Schwann cells, the perineurium, the epineurium, and the capillaries. This became possible when nerve sections were stained with silver and counterstained with fuchsin. The mesodermal tissue is the first

to react following any nerve injury by proliferating. This proliferation takes place at the site of the lesion and from there on into the gap between the severed nerve segments, in the degenerated distal nerve segment, and in the perineurium and the epineurium of the central as well as the distal nerve segment. Regenerating nerve fibers follow the path of proliferating histiocytes and collagenous fibers. Wherever this proliferative mesodermal reaction takes place, regenerating nerve fibers may be seen following the course of the mesodermal fibers, even deviating into the epineurium of the distal segment or, as retrograde fibers, into the epineurium of the central segment, or invading the surrounding muscles. This observation appears to be evidence against the generally accepted theory that the regenerating distal segment of a cut nerve exerts a chemotropic influence on regenerating nerve fibers growing out of the end of the central segment.

The mesodermal tissue plays a primary role in the organization of autogenous and homogenous grafts in laying down a scaffolding which is followed by the regenerating nerve fibers. Depending upon the degree of survival of the mesodermal elements in the graft and the degree of necrosis which took place, this scaffolding follows the original nerve structure or becomes irregular, deviating, and confused in its course, and thus influences the course and the efficacy of the regenerating nerve fibers.

A very definite contusion effect within the nerve may be found following gunshot injuries which do not interrupt the continuity of the nerve. Extensive traumatic damage is present for a long distance centrally and peripherally from the site of trauma. It leads to a process of necrobiosis and dissolution of the ectodermal elements with survival of the mesodermal elements, and results in an obliteration of the endoneurial structure and a marked confusion in the course of the regenerating mesodermal and nerve fibers.

Young and Medawar in England and Tarlov in this country carried out a series of experiments, using concentrated blood plasma gel as a method of uniting divided nerve ends. There is no doubt that this method can be used to advantage in experimental nerve sections and in the human being when the nerve ends can be approximated easily. The microscopic evidence of the advantages of plasma gel over other suture material is quite definite, and it remains to compare a considerable series of operations upon animals, using plasma and fine silk suture material, both microscopically and for the return of function in the denervated muscles. Plasma gel has a definite place as a

suture material when nerve transplants are employed, particularly in the smaller nerve trunks such as the digital nerves

There were many cases of causalgia observed among patients with peripheral nerve injuries in World War II. There is some confusion as to what constitutes this condition mainly because the classic description first made by S. Weir Mitchell was not adhered to strictly. There are some who believe that causalgia, Sudeck's atrophy, painful osteoporosis, and other so-called "minor causalgias," or painful "phantom limb" are different clinical manifestations of the same underlying disorder. Mayfield and Devine presented the most accurate and careful study of cases of causalgia which they encountered. They correlated the symptoms and trophic changes with the blood flow in the extremity affected, and the results of their studies suggest that the pain of causalgia does not result from alteration in the blood flow, because some patients were found in whom the injured extremity was in a state of vasodilatation, while others showed vasoconstriction. Sympathectomy gave prompt relief regardless of the state of the blood vessels, a fact which is somewhat difficult of explanation.

Seddon called attention to the severity of the injury to a peripheral nerve from traction without disruption of the anatomical continuity of the nerve trunk. For example, the peroneal nerve may be stretched tightly across the head of the fibula. He pointed out that patients with this condition showed evidence of severe damage by a delayed return of function or no return whatever. This type of injury to the elements of the nerve trunk is similar to the effects of concussion from a high velocity bullet passing near a nerve trunk without interrupting its anatomical continuity. The difference between this type of traumatic degeneration and true wallerian degeneration has been described and emphasized by Hiller and his colleagues.

The question of the opportune time to operate upon peripheral nerve injuries was widely discussed during World War II, mainly because Seddon stated that an interval should elapse between the receipt of the injury and repair of the divided nerve trunk. With this all inclusive viewpoint, American neurological surgeons, who had had experience with operations upon peripheral nerve injuries and long continued follow up studies upon the results, would not agree. Certainly, a patient who receives a laceration of the wrist with division of the flexor tendons and the ulnar or median nerves by thrusting his hand through a window glass, should be operated upon as quickly

as possible after the injury, and the tendons and nerves should be promptly repaired. If the same injury has resulted from an accident by which the wound was severely contaminated, and if the surgeon first encounters the patient from 12 to 24 hours later, the chances for the development of infection are serious, although infection might well be avoided by meticulous cleansing of the wound and the use of chemotherapy. But again, the tendons and nerve ends should be repaired immediately. If infection develops the nerve ends are approximated, and the amount of neuromatous tissue to be resected later will be less and traction of the nerve ends will be prevented. If, however, there was destruction of a nerve trunk with a large gap in continuity which can not be bridged by the usual methods of obtaining end-to-end apposition, then repair may be deliberately delayed. Certainly, repair should be delayed if the wound is grossly contaminated and infection is highly probable, regardless of whether or not the ends can be approximated by movements of the adjacent joints.

It was shown experimentally that trophic ulcers developed invariably when nerve ends were allowed to remain separated, but when the ends were approximated, even when it was accomplished by nerve transplants, ulcers did not occur. The amount of atrophy which developed in the muscles was certainly less in the experimental animals under the same conditions. Clinically, there is no doubt that the best results have been obtained, regardless of the nerve involved, when the nerve ends have been apposed as early as possible after the injury.

It has been shown experimentally that if a denervated muscle can be stimulated electrically rather constantly, atrophy can be prevented. In the human patient this is difficult of proof, but it has been generally accepted that electrical stimulation to the denervated muscles, plus intensive massage, active and passive movements, and proper splinting improve recovery of the patient considerably.

COMMENT

Neurological surgery is a specialty of surgery. A background of fundamental knowledge of neurology is a prime requisite, and to a lesser degree ophthalmology and roentgenology. Good training in the basic sciences is necessary for every good surgeon, whose aim should be to restore his patient as nearly as possible to the physiological normal. There is no reason to assume that the neurological surgeon is an expert neurologist. Certainly, the surgeon would not agree that the

neurologist can, without proper training and persistent effort, be an expert surgeon. There should and must be a co-ordination of efforts, a meeting of minds, and exchange of ideas directed toward giving the patient the best possible care and advancing the possibilities of treatment for the neurological diseases. The contributions which each individual can make in his chosen field of endeavor must be recognized and utilized for the common goal. The neurological surgeon must not be diverted from that goal by gadgets and surgical stunts. Preparation for wars must include the medical profession which has given more to the military services than any one other professional class in the past. We must not again allow 1,500 military medical men, out of touch and disinterested in the progress of medicine, to agree in principle and obstruct in practice the objectives of the civilian profession in the care of the wounded.

EYE

Proptosis Due to Neuroblastoma of the Adrenal Cortex (Hutchinson's Syndrome) Report of a Case
RONALD A COX *Arch Ophthalmol*, Chic 1948, 39 731

A male child 15 months old revealed on first examination a proptosis of the left eye, enlarged glands at the angles of the jaw, a mass in the upper left quadrant of the abdomen, and a striking anemia (hemoglobin concentration, 56 per cent). The roentgenogram showed extensive destruction in the left ethmoid, sphenoid, and frontal bones, and radiolucent areas in the upper end of each femur and humerus. The patient became increasingly lethargic, and death occurred 40 days after admission. The diagnosis of neuroblastoma of the left adrenal cortex was confirmed at autopsy.

In neuroblastoma of the adrenal cortex the orbit is always involved, and frequently the eye gives the first indication of the disease. Invariably a fatal termination follows in from 2 to 5 months. Only 291 cases have been previously reported. The average age for the Hutchinson type is 3 years, 10 months.

Tumors composed of undifferentiated neural cells, such as neuroblastoma, are highly malignant, while tumors from differentiated neural cells (ganglioneuroma, paraganglioma, pheochromocytoma) are benign. In the Pepper syndrome, the neuroblastoma predominantly involves the mesenteric lymph nodes and liver, in the Hutchinson type, the skull and periorbital area are particularly affected.

The diagnosis is probable in young male children when pain in the bone, bulging of the eyeball, an abdominal mass, and anemia are present. To be differentiated are lymphatic leukemia, lymphosarcoma, chloroma, Hand-Schüller-Christian disease, and Ewing's sarcoma. Thus far, no treatment has proved effective. Surgical intervention is usually followed by death within a short period.

JAMES E. LEBENSOHN, M.D.

Allergic Conditions of the Eye Keratitis Rosacea
VERA B. WALKER *Brit J Ophthalmol*, 1948, 32 759

The term "allergy," as applied by the author, denotes an altered reaction rather than a hypersensitivity. Most allergic conditions are acute in onset and, if recognized and treated at once, clear up quickly, often within a few minutes or hours, leaving no permanent damage to the tissues involved, but it must be realized that once a tissue has remained in an abnormal physiological condition for some time, as in recurrent keratitis or iridocyclitis, there are secondary changes due either to inflammation or infection, which must be healed by routine treatment, although the allergist may be able to help in

preventing a recurrence of the lesions. It is not known why one tissue rather than another should be the "shock" tissue in any patient, and we are left wondering whether some damage, possibly congenital and probably traumatic, must have been a forerunner of the condition. The presenting clinical signs and symptoms will depend upon the underlying structures of the various tissues involved. Depending on which tissue is sensitized to the offending allergen, i.e., the "shock" tissue, we may see angioneurotic edema, blepharitis, conjunctivitis, keratitis, iritis, iridocyclitis, keratitis rosacea, retinal hemorrhage or detachment, choroiditis, glaucoma, cataract, or migraine.

Keratitis rosacea, a relatively common abnormality of the skin of the face of adults between the ages of 20 and 50 years, is frequently accompanied by ocular manifestations, varying in degree from a mild conjunctivitis, through all the states of blepharoconjunctivitis, episcleritis, and keratitis, to eventual visual incapacity. As numerous as are the lists of possible causes of keratitis rosacea, almost all authors agree that the condition is metabolic rather than local, digestive upsets, deficiency diseases, and hormonal disorders all play a part and must be appropriately treated, but even after all these have been corrected and all bacteria removed, there is still an underlying condition which predisposes to recurrence. From a survey of 76 cases, it is seen that allergy plays a fundamental part in the syndrome.

Local treatment consisted of (a) removal of secondary infection with penicillin ointment, sulfa-thiazole, or antiseptic ointments, (b) the application of dithranol (0.1 per cent dihydroxyanthranol) cream to the skin twice daily for at least 2 weeks. General treatment consisted of desensitization with specific antigens by a 6 weeks' course of injections, nonspecific desensitization of others with histamine azo-globulin by 10 graded intramuscular injections (0.05 cc, 0.1 cc, 0.2 cc, 0.3 cc, 0.4 cc, 0.5 cc, 0.6 cc, 0.7 cc, 0.8 cc, and 1.0 cc) at the rate of 2 injections a week for 5 consecutive weeks. If at a later date a recurrence of symptoms of either eye or of the face occurs, then 0.5 cc of histamine azo-globulin is given immediately, and repeated after 4 days.

It appears that 70 per cent of the patients with keratitis rosacea have not had a recurrence of symptoms within the 2 years following their treatment, many of these are still symptom free after 3, 4, or 5 years. It is significant that there is a difference between the group in which specific allergens were found, and the group in which all patients were treated with histamine. In the first group, the percentage of patients who remained symptom free was nearly twice as great as in the second group.

The author emphasizes the urgency of referring all cases of keratitis rosacea to the allergists for investigation, as well as other cases of keratitis of unknown origin, especially in patients with a family history of acne, eczema, and urticaria, even though their own skin manifestations have not yet become obvious

MICHEL LOUTFALLAH, M D

Allergic Conditions of the Eye Migraine VERA B WALKER *Brit J Ophthalm*, 1948, 32 764

Migraine is of importance to ophthalmologists, first because all humans with severe headaches, from whatever cause, eventually find their way to an eye hospital to be checked for refractive errors, and second because 50 per cent of individuals with migraine have eye symptoms, often very severe in onset

The study was made on 100 consecutive cases of migraine investigated during the period from 1943 to 1947, and 54 were proved to be allergic either by clinical trials, by skin tests or, more often, by both methods. With each patient, an attempt was made to produce a migraine attack before prophylactic treatment was begun. Typical examples of such patients' histories were given and, when the allergy was confirmed by clinical trial, the treatment consisted in avoidance of contact with the offending allergen, or desensitization

While these cases show that if a patient has allergic migraine he can be helped tremendously by avoiding those allergens to which he is specifically sensitive, or by being desensitized, it must be remembered that the other 46 per cent of patients should be excluded from these somewhat tedious investigations as they can derive no benefit from them, they do not belong to allergic families and do not present other manifestations of allergy themselves. Realizing that all patients are reluctant to give a detailed family history or an accurate personal history, other clinical methods for separating the 54 per cent allergic from the 46 per cent non-allergic patients have been sought and, during routine general examinations, significant differences of systolic blood pressures in the two groups were observed, there was no marked difference in pulse pressures. From the study, it becomes clear that although all migraine sufferers do not have low systolic pressures and all migraines are not of allergic origin, if a patient with true migraine has a low systolic pressure, then allergy should be suspected and treated appropriately

The author concludes that migraine in patients with low systolic pressure are manifestations of allergy

MICHEL LOUTFALLAH, M D

Symposium Corneal Transplantation Selection of Cases R. TOWNLEY PATON *Am J Ophthalm*, 1948, 31 1365

The author stresses that each case being considered for corneal transplantation must be evaluated individually, but he lists a few basic considerations

Environmental factors, age, and the physical condition of the patient are carefully considered. If

other more simple surgery can improve vision, corneal transplantation should be reserved

The cases for surgery are classified as

1 Those favorable to improvement of vision. These should present no active disease, no increased intraocular tension, and no vascularization. Vision should be less than 20/200 corrected

2 Those partially favorable to improvement of vision. They may have some vascularization of the cornea and an opacity may be present but it should be surrounded by clear cornea

3 Those unfavorable to improvement of vision. These would present amblyopia, marked nystagmus, corneal scars from lime, or severe burns

4 Those amenable to cosmetic improvement, the transplantation being used to replace the old tattooing operation

5 Those presenting descemetocoele. The results in these cases are excellent if other factors are favorable

6 Cases in which preliminary surgery or treatment is necessary

EARL H. MERZ, M D

Symposium Corneal Transplantation Technique

JOHN M McLEAN *Am J Ophthalm*, 1948, 31 1370

In this report the actual surgical techniques of corneal grafting were discussed. A résumé of the history of corneal grafting showed progress from 1887 to the present time

The various techniques then discussed were total keratoplasty, rotating autokeratoplasty, superficial lamellar keratoplasty, and partial penetrating keratoplasty. The partial penetrating keratoplasty is most successful in ordinary cases. In this operation a relatively large graft is used and held in place by sutures in the cornea but not in the graft. Either round or square grafts are used, and the anesthesia is local. The pupil is widely dilated. The postoperative care is similar to that of cataract, with dressings only every 4 to 5 days

EARL H. MERZ, M D

Symposium Corneal Transplantation Complications RAMON CASTROVIEJO *Am J Ophthalm*, 1948, 31 1375

The author divides the complications into several groups and discusses each group

1 *Complications during the operation.* The corneal epithelium may be damaged on either donor or recipient. This does not interfere with surgery but increases the possibility of infection. The incision may not be centered on the cornea, or a thin cornea may be perforated when the graft is outlined. In either case one may proceed with or postpone the procedure, as desired. If the suture is broken during the operation it can be tied, but the knot must be drawn away from the graft to prevent opacification. The lens may be injured during the operation. The section should be completed and the lens material removed with as much capsule as possible. Extra suturing is needed to prevent vitreous prolapse. If the pupil is not fully dilated after section and cannot be dilated, an iridectomy is advised

2 Complications during the postoperative period

The graft may be completely displaced outside of the corneal opening. Reimplantation is necessary, with added suturing if possible, or a new graft is prepared. If this is impossible a conjunctival graft is advised. If an iris prolapse occurs it is advisable to wait 3 weeks and then incise the iris and suture the graft. Prophylactic treatment should be started for infection.

Synechiae are very common and require freeing either with mydriatics, myotics, or surgery. Surgery is not attempted before the fourteenth postoperative day nor after 3 weeks. The procedure is given in detail.

3 Infections. Glaucoma, vascularization, inflammation, and edema are all discussed briefly and their treatment is described. LARK H. MERZ, M.D.

Symposium Corneal Transplantation Physiology

A. F. MAUMENÉ and WALTER KORNBLUTH *Am J Ophthalm.*, 1948, 31: 1384

The first portion of this article deals with 4 separate experiments on the fate of the grafted cornea. The conclusions drawn were as follows:

1. There is no massive replacement of the cells in an autogenous or homogenous graft at any time.

2. The wandering macrophages of the recipient animal probably contribute from the beginning in a limited degree to the replacement of the donor cells in a corneal graft.

3. Viable donor cells are essential for a successful take of a transplant, at least for the first 2 weeks after operation, until the dependence of the donor graft on the recipient cornea is fully established. The donor cells are not essential to the clarity of the graft once the tissue has become firmly attached to the recipient cornea.

The second portion of the article deals with factors which influence the results of keratoplasty. The factors are divided into the condition of the grafted tissue, the status of the recipient cornea, and the operative complications.

The authors conclude that the donor cornea should be viable tissue and as untraumatized as possible. The continued viability of the graft is not essential after the second postoperative week. The recipient cornea should not be completely opaque nor edematous. Good apposition of the graft should be obtained. LARK H. MERZ, M.D.

Symposium Corneal Transplantation Results

W. C. OWENS, J. J. IRANK, BRIAN LEAHEY, P. E. MESSIER, and OTHERS *Am J Ophthalm.*, 1948, 31: 1394

A statistical study has been made of the results of 417 corneal transplantation operations.

The graft remained clear in 36.5 per cent of the cases.

The percentage of clear grafts varied greatly with the cause of the corneal opacity. The best results were obtained in cases of keratoconus (65.2%), hereditary dystrophy (58.8%), interstitial keratitis

(49.0%), and nonspecific inflammatory scars (46.9%). Poor results were obtained in cases of active keratitis or corneal ulcer (23.1%), scars from chemical burns (20.8%), trauma (18.2%) and gonococcal ulcers (8.7%). No clear grafts were obtained in cases of Fuch's dystrophy.

The larger the size of the corneal opacity and the greater the extent of corneal vascularization, the less were the chances of obtaining a clear graft.

In a group of 79 cases selected as having the most favorable prognosis, 68.3 per cent of the grafts remained clear.

Of 229 patients with preoperative vision of 20/200 or less, 36.2 per cent obtained a postoperative vision of 20/100 or better. A group of 58 patients with preoperative vision of 20/200 or less was selected as having the most favorable prognosis. Of these, 55.2 per cent obtained a postoperative vision of 20/100 or better.

The visual results after corneal transplantation in patients with preoperative vision of 20/100 or better do not warrant the risk of the operation.

LARK H. MERZ, M.D.

Anterior Flap Sclerotomy with Basal Iridencleisis, A Preliminary Report

H. B. STALLARD *Brit J Ophthalm.*, 1948, 32: 753

The operation proposed consists in reflecting a conjunctival flap, fashioning a scleral flap hinged on the corneoscleral junction, a limited cyclodialysis, and the inclusion of a basal tongue of iris between the lips of the sclera, leaving the sphincter pupillae intact. The operation has been performed in 29 cases of chronic glaucoma and in 2 cases of acute congestive glaucoma, with encouraging results. Iritis occurred 3 weeks after operation in one case. In this respect the postoperative course differs from that following the trephine operation in which some degree of iritis commonly occurs. The technique is as follows:

A suture is passed through the tendon of the superior rectus muscle and is clamped down in the frontal region. A subconjunctival injection is made about 3.5 mm from the limbus from 10 to 2 o'clock so as to raise the episcleral tissues and conjunctiva. The conjunctiva is grasped by smooth forceps 2.5 mm anterior to the insertion of the superior rectus. The conjunctiva is then snipped for about 5 mm down to the sclera. The blades of the scissors are spread and the conjunctiva is undermined laterally on both sides. The conjunctiva and episcleral tissues are then undermined down to the limbus. One blade of the scissors is now passed underneath the conjunctiva on the temporal side and slightly downward, and the conjunctiva is cut for about 8 mm from the midline. Similarly, another incision is made on the nasal side. The conjunctival flap thus formed is turned forward and downward over the cornea with a few strokes of a small applicator. With a double-pronged conjunctival hook, the conjunctival flap is now held downward by the assistant. With a few strokes of

the corneal splitter, a clear view of the episcleral tissue just above the limbus is obtained. Any bleeding points can be checked by a touch from a heated probe. This probe also seals off any superficial episcleral vessels in the line of the scleral incision to be made 5 mm long, 2 mm above and concentric with the limbus. A fine scleral hook is inserted into the sclera in the 12 o'clock meridian 2 mm above the limbus, this steadies the eye during the scleral incision and also retracts the anterior lip of the incision. The scleral incision is made with either a sclerotome or a ground-down cataract knife vertically in the sclera. When the ciliary body shows in the incision, any remaining scleral fibers are divided by a few light strokes with the point of the cataract knife. The scleral hook in the anterior lip of the scleral incision is now slightly raised and a cyclodialysis spatula is passed through the center of the incision into the anterior end of the suprachoroidal space, then on to separate the scleral spur and to enter the anterior chamber. In the anterior chamber, the spatula is moved in turn to each side of the scleral incision so as to effect a cyclodialysis 5 mm long. Aqueous flows out of the incision during this procedure. The cyclodialysis spatula is withdrawn. With the scleral hook still in place, one blade of the scissors is passed on the flat into one end of the scleral incision for 2 mm. The blade is then rotated so that its cutting edge faces forward, and its blunt end is level with the corneoscleral junction and 1 mm nearer to the midline than the end of the scleral incision. The blades of the scissors are closed and a converging cut is made in the sclera down to the limbus. A similar procedure is done at the other end of the scleral incision. When this is completed, a hinged scleral flap is made, based on the limbus. A pair of iris forceps, closed, is now introduced into the center of the incision, and the iris is grasped 2.5 mm above the pupillary margin and drawn up into the center of the scleral wound as the conjunctival flap is being drawn down by the assistant. A snip about 1.5 to 2 mm long is made with fine blunt-ended scissors in the iris immediately in front of the forceps. One blade of the scissors is passed through the snip toward the temporal side, and a cut 3 mm long is made toward the iris root. A blade of the scissors is then directed through the iris incision nasally toward its root, and a cut is made for about 3 mm. The folded tongue of iris based on its root is then laid on the sclera so that about 2.0 to 2.5 mm projects above the upper lip of the scleral incision. It may be necessary, in some cases, to reposit the iris, often it is sufficient to apply the iris repositor to the upper part of the cornea and make a downward stroke over its surface.

Postoperative treatment has been simple. There is no need for digital massage, atropine is used at the first dressing and omitted thereafter. The patient is allowed up in a chair on the fourth day and is allowed to leave the hospital on the eighth

day. The anterior chamber is reformed on the day after operation. Small hyphema occurred in 6 cases without further complication.

MICHEL LOUTFALLAH, M D

Studies in Experimental Ocular Tuberculosis. The Effect of "Promin" and "Promizole" on Experimental Ocular Tuberculosis in the Immune-Allergic Rabbit. ALAN C WOODS and EARL L BURKY. *Arch Ophthalmol*, Chic., 1948, 39 471

Promin and promizole are sulfonamide compounds which have been shown to have a deterrent action on tuberculosis in experimental animals. The present study concerns the effect of these drugs on ocular tuberculosis in immune-allergic rabbits. Rabbits were inoculated in the groin with a virulent human strain of tuberculosis which caused a definite hypersensitivity to tuberculin and a resistance to reinoculation. Inoculation of the anterior chamber of such immune-allergic animals was followed by the formation of small, hard tubercles on the iris and cornea with a moderate inflammatory action which became inactive in from 3 to 6 months. Such animals were treated with 1.5 gm per rabbit per day of the drugs, beginning the sixth week after inoculation of the anterior chamber. After 3 months of treatment the eyes were sectioned for histologic study. In another similar group the uveal tract was removed after treatment and, after appropriate extraction, injected into the anterior chamber of normal rabbits.

The treated rabbits began to improve after 3 weeks of treatment and by the twelfth week, at which time the control eyes were markedly inflamed, the ocular tuberculosis in the treated group was almost completely inactive. Promizole and promin seemed equally effective although promin was the more toxic. Sections of the eyes indicated that the untreated animals had many more lesions which were larger and more active than the few lesions found in the treated animals. Inoculation of the uveal tract extract into the anterior chamber resulted in ocular tuberculosis in all animals injected with material from the control group. The uvea of one of the 3 rabbits treated with promin produced ocular tuberculosis upon inoculation, but only after the very long incubation period of 2 months. The uvea of rabbits treated with promizole did not produce tuberculosis on inoculation. It is concluded that both promin and promizole have a definite deterrent action on ocular tuberculosis in the immune-allergic rabbit but do not produce a complete cure. The action may be due to either a degradation or attenuation of the virulence of the organisms, allowing the reaction of the host to become more effective, or to a direct bactericidal action on the bacteria.

FRANK W NEWELL, M D

Bacitracin in Ocular Infections. J G BELLOWES and C J FARMER. *Am J Ophthalmol*, 1948, 31 1211

Ocular tissues have a tolerance to bacitracin in concentrations up to 1,000 units per milliliter of saline solution given externally and up to 100 units

mine for these tests in simple glaucoma, but there is danger in narrow-angle glaucoma or preacute glaucomatous eyes

PRESSOR CONGESTION TEST

This test is the lability test of Bloomfield and Lambert, based on a combination of the cold pressor test and the jugular compression test

An initial tonometric reading is made with the patient in the supine position. The sphygmomanometer cuff is placed around the neck of the patient while one of his hands is immersed to the wrist in chipped ice and water. The cuff is inflated to between 50 and 60 mm Hg, for 1 minute. A reading is made and repeated after the pressure is released and the hand has been removed from the water.

In 192 normal eyes, this test gave an average increase of 3.6 mm Hg (range -2 to +9 mm).

The pressor-congestion test tends to increase the intraocular pressure, particularly when there is any defect in the mechanism controlling intraocular pressure. The author also believes that this test increases the tonus of the extraocular muscles and this would raise the intraocular pressure too. An increase over 9 mm Hg or the elevation of tension over 30 mm is suggestive of chronic simple glaucoma according to Bloomfield and Lambert. In this series of glaucomatous eyes, the pressure exceeded this 9 mm in less than one-half of the cases and the normal series revealed a pressure of 30 mm or over in only 20 per cent of the eyes. The anterior chamber puncture test was normal in 4 of the cases with tension of 30 mm or more.

WATER AND PRESSOR CONGESTION TEST

This test was performed 2 hours after breakfast or lunch on normal and glaucomatous eyes. The tension was recorded, 1 liter of water given, and the pressor congestion test applied in 0.5 hour.

The average increase of intraocular pressure in 71 normal eyes was 5 mm Hg (range -3 to +10). Three eyes revealed a pressure of 38 mm Hg.

The results in glaucomatous eyes reveal that a greater increase in tension is shown with this test than with any of the others. Further comparison of these tests on the same eyes seemed to substantiate the earlier findings both in normal and glaucomatous eyes.

An increase of over 10 mm Hg of pressure would certainly indicate a positive reaction. A negative result does not rule out glaucoma.

CONCLUSION

Combined water and pressor congestion tests give higher readings than either test alone.

In the water tests, a positive result represents an increase of over 9 mm or a rise to over 32 mm; in the pressor congestion test a positive result represents an increase of over 9 mm or a rise to over 33 mm; in the combined tests a positive result represents an increase of over 10 mm or over 38 mm Hg.

The caffeine test was of no value.

Mydriasis is safe in simple glaucoma but has not given a significant rise in pressure. In narrow angle eyes it is the test of choice, but it should be controlled by miotics.

In borderline cases of simple glaucoma repeated tonometry is an important diagnostic test.

J. WOODHULL OVERTON, M.D.

The Pressor Test for Glaucoma GEORGE T. STINE
Am J Ophth, 1948, 31: 1203

This author confirmed the work of Bloomfield and Lambert as to the reliability of the lability pressor test for chronic simple glaucoma of the wide angle type.

The pressor test is based upon vascular variations within the globe in which a sudden strain is introduced so that increased lability manifests itself clinically. This test allows for an increase of blood flow into the eye and a mechanism for decreasing the outward flow of blood.

The patient is seated at a 30 degree angle from the horizontal. A sphygmomanometer cuff is applied around the neck, pontocaine (1½%) is instilled into the eyes, and the tension is measured (Schiotz). The hand and wrist are placed in cold water (4°C) and the sphygmomanometer cuff is inflated to between 50 and 60 mm Hg for 1 minute. The tension is taken at that time.

Patients with normal and abnormal eyes were used. The narrow angle cases were chosen mostly for this work but some wide angle cases were also checked.

The mean rise in pressure in the normal group, wide angle group, and narrow angle group was 1.01, 13.82, and 2.0 mm Hg, respectively. This seems to be a valid test for wide angle glaucoma. Criteria for a positive test were (1) a rise greater than 9 mm of Hg and/or (2) a rise to more than 30 mm of Hg. In this series of 35 patients, only 4 failed to show a rise above 30 mm of Hg.

The increase in tension in narrow angle glaucoma approximates the normal so these two groups cannot be differentiated with this test. In 112 normal eyes tested by Bloomfield in this series, there were only 2 false positives. Narrow angle glaucomas are diagnosed on the basis of visual fields, the fundus picture, and mydriasis tests. The mean rise in pressure in the normal group, the narrow angle group, and the wide angle group under mydriasis was 1 mm Hg, 14.33 mm Hg, and 3.60 mm Hg, respectively. Every eye classified as narrow angle glaucoma gave a positive test.

The pressor test seems to be a good clinical test for diagnosing the wide angle type of chronic simple glaucoma. It is thought that the rise in the wide angle group is due to pathology in the drainage mechanism in the trabecula and canal of Schlemm while in the narrow angle group the iris base blocks the angle. Patients who had a positive pressor test despite normal tension under miotic were all found to have normal visual fields and visual acuity. However, the pr

tients who had a negative pressor test had been without appreciable field loss for some time. There were only 14 eyes in this series.

The author summarizes his article as follows:

1. The pressor test should be used in conjunction with a gonioscopic examination for the best results.
2. The pressor test seems reliable for the detection of the wide angle type of chronic simple glaucoma, while mydriasis was the method of choice for the narrow angle type.
3. The mechanisms involved seem to be entirely different for the two groups.
4. The pressor test may be of value in progress of the visual field loss in the wide angle group.

J. WOODHULL OVERTON, M.D.

EAR

Observations Upon the Loudness Recruitment Phenomenon, with Especial Reference to the Diagnosis of Disorders of the Internal Ear and Eighth Nerve. M. R. DIX, C. S. HALLPIKE, and J. D. HOOD. *J. Lar. Otol.*, Lond., 1948, 62: 671.

The authors present the results of, and their observations upon, loudness balance tests carried out in 30 cases of unilateral deafness due to Ménière's disease and in 20 cases of degeneration of the eighth nerve, due to neurofibroma of the eighth nerve and other varieties of space occupying lesions of the cerebellopontine angle. This choice of the two disorders was made by the authors because in the one, Ménière's disease, the primary lesion is now known to affect the endolymph system of the cochlea with its contained cochlear end-organs, while in the other, the primary lesion is of the cochlear nerve fibers within the internal auditory meatus.

The 30 cases of Ménière's disease all gave a characteristic history of paroxysmal vertigo, deafness and tinnitus, with the deafness substantially limited to one ear in the great majority. None gave any history of head injury, and general neurological examination revealed no abnormalities. On the other hand the 20 cases of eighth nerve degeneration which were studied included 11 cases of neurofibroma of the eighth nerve, in all of which the clinical diagnosis was confirmed by operative or postmortem findings. In addition, the remaining 9 cases studied in the category were other varieties of cerebellopontine angle lesions exhibiting well marked involvement of function of the eighth nerve and of these, 6 diagnoses were confirmed by operative or postmortem findings. Thus, the cases studied would appear to be well authenticated.

The loudness recruitment pattern with the audiograms, in 3 representative cases of their results in the 30 cases of Ménière's disease, are shown in the article. The authors state they found loudness recruitment to be present and complete in all 30 cases of Ménière's disease. The test results in 5 characteristic cases of eighth nerve degeneration are also shown, and the authors' summary of the results in the cases of eighth nerve degeneration showed loud-

ness recruitment to be absent in 14 of the 20 cases. In the remaining 6 cases a slight amount of recruitment was present, and in some of these there was found a fixed upper loudness limit in the affected ear.

Thus, the loudness recruitment was shown to be characteristically present in a disorder of the end-organ of hearing, and to be characteristically absent in a disorder of the cochlear nerve fibers, in the latter case, a type of response which is identical with that found in middle-ear deafness.

Since this latter finding sharply contravenes the existing views, namely, those of Lonente de No and Fowler, upon the neurological mechanism of recruitment, the authors advance new hypotheses in explanation of their results, based upon recent experimental work on the physiology of hearing.

According to the authors, their finding of an unvarying occurrence of the recruitment phenomenon in Ménière's disease, a disorder of the end-organ of hearing, appears to be related to Pumphrey and Gold's theory, based on their recent experimental work, that the microphonic potentials of the cochlea arise somewhere in Corti's organ and play a vital part in determining both its sensitivity and frequency selectivity. The essayists find it pertinent to observe that the very nature of the recruitment phenomenon corresponds very well with a type of derangement well known in certain microphones. The example given is a carbon microphone which, in good order, yields an electric response which is linear over a wide range of sound pressures. However, in a faulty carbon microphone the response at low sound pressures may be very defective, while at high pressures it may be nearer the normal value.

The authors suggest that the absence of loudness recruitment in degeneration of the eighth nerve can be explained on the following assumptions:

1. That the nerve degeneration engendered by tumor pressure or infiltration is an evenly diffused one with a definite fiber survival rate.
2. That the relationship between stimulus intensity and loudness sensation depends upon a definite fractional increase in the number of activated cochlear nerve fibers which accompanies each ascending step of the loudness scale.

EUGENE L. DERLACKI, M.D.

Lempert Decompression Operation for Hydrops of the Endolymphatic Labyrinth in Ménière's Disease. JULIUS LEMPERT. *Arch. Otolaryng.*, Chic., 1948, 47: 551.

Ménière's disease has as its basic pathology a hydrops of both the vestibular and cochlear portions of the endolymphatic system. Treatment should be designed to relieve both the vertigo, which is vestibular in origin, and the tinnitus which is most likely cochlear in origin.

Partial section or electrocoagulation of the vestibular portion of the endolymphatic system, through a fistula created in the external semicircular canal, usually relieves vertigo but seldom relieves tinnitus. The histologic study of experimentally fenestrated

chus monkeys demonstrates that destruction of the vestibular endolymphatic system may occur without degeneration of the remaining endolymphatic system and organ of Corti

An operation to effect complete degeneration of the endolymphatic system is described. The tympanic cavity is approached endaurally by eversion of a skin flap from the posterior wall of the canal, and enlargement of the bony meatus by a dental burr. The posterior one-half of the tympanic membrane is then reflected anteriorly and the opening is widened at the annulus tympanicus. The long process of the incus is severed and the stapes is removed. A burr is then used to remove the round window membrane and enlarge the window. The various steps are described and illustrated in detail.

Of the 10 patients operated on by this technique, 9 were freed of vertigo and tinnitus and 1 was freed of vertigo only.

MOUTH

Facial Injuries Followed by Meningitis, with Recovery A J B PHILLIPS *Brit J Plast Surg*, 1948, 1: 172

The author's patient suffered severe, soft tissue injuries in a fall, face foremost, from a height of 17 feet. Multiple lacerations extending in the midline from the hairline to the symphysis menti were impregnated with coal dust, those of the tip of the nose, both lips, and chin were full thickness in depth, and the laceration of the forehead exposed the frontal bone but there was no visible fracture.

Twelve hours after the injury, after a preoperative dose of 500,000 units of penicillin and antitetanic serum, the wounds were debrided and sutured in layers. The only fractures which were noted were of the nose.

Penicillin was administered regularly. The following morning, a fever of 100 degrees was noted with a productive cough. A course of sulfadiazine was started. This was discontinued after 6 gm had been administered because of cyanosis. A serous fluid from the nostrils was designated as cerebrospinal rhinorrhea. The general condition and the condition of the facial wounds were satisfactory and the temperature was normal on the third day. The patient had had 2,700,000 units of penicillin intramuscularly and 6 gm of sulfadiazine orally.

On the fourth day, loss of consciousness occurred with a temperature of 103.6 degrees, stertorous breathing, and marked rigidity of the neck. Lumbar puncture revealed turbid fluid under pressure and culture later revealed the *Staphylococcus aureus*. Penicillin (15,000 units) was given intrathecally upon diagnosis of the meningitis, an additional amount was given intramuscularly and sulfadiazine was given orally. Recovery began within several hours.

In the treatment of the established meningitis, 8,600,000 units of penicillin were given intramuscularly, 90,000 units of pure penicillin were given intrathecally, and 24 gm of sulfadiazine were given

orally. Recovery was rapid and on the seventeenth day when the temperature and pulse were normal, penicillin was discontinued. The patient felt good from the tenth day onward and was allowed up on the twenty-first day. Up to the present time no abnormal symptoms, mental or physical, have resulted from the meningitis.

NECK

The Clinical Aspects of Chronic Thyroiditis HOWARD PATTERSON and GEORGE STARKEY *Ann Surg*, 1948, 128: 756

Chronic thyroiditis is not a rare disease, and it is most important for the patient that the situation is fully recognized at operation. Chronic thyroiditis may be divided into three groups: (1) struma lymphomatosa of Hashimoto, (2) struma fibrosa of Riedel, and (3) the giant cell type of DeQuervain.

Hashimoto's disease is characterized by a diffuse lymphocytic involvement of the thyroid gland, it is very rare in males and occurs chiefly in women at or near the menopause. Adhesions to the surrounding structures do not occur, but the thyroid is usually diffusely enlarged, pressure symptoms are mild, and the patient is apt to be myxedematous. The author performs symmetrical conservative thyroidectomy followed by x-ray therapy.

Riedel's disease, or struma fibrosa, occurs in both sexes but predominantly in women. The process is at first localized and spreads over the gland, the involved portion is pale and stony hard with dense masses of fibrous tissue, and is usually very adherent to the surrounding structures. Freeing of the trachea by excision of the isthmus is all that is indicated. The disease is often confused with malignancy, and unwise and harmful surgery may follow.

The giant cell type of thyroiditis of DeQuervain does not involve the thyroid gland diffusely, but there is some tendency toward adherence to the surrounding structures. The pathological picture may closely simulate tuberculosis. X-ray therapy following positive diagnosis may be the treatment of choice.

F J LESEMANN, JR, M D

The Frequency of Hyperthyroidism, Its Causes and Therapy (Ueber die Häufigkeit hyperthyreotischer Zustandsbilder, ihre Ursachen und ihre Behandlung) J WALDSCHÜTZ *Wien med Wschr*, 1948, 98: 510

A comparison is made between a group of patients with hyperthyroidism treated between 1919 and 1921 and another group treated between 1945 and 1947, with special attention to relations between the disease and the nutritional changes, and the mental and physical traumas caused by the war.

Exophthalmos was recorded in 19 per cent of the first and only 11 per cent of the second group. The receding frequency of this phenomenon has been reported by several other writers.

Nystagmus, never found in the first group, was reported in 4 per cent of the second group and was apparently of central origin.

An enlargement of the thyroid gland was present in 75 per cent of the first and 65 per cent of the second group. In most cases the gland was smaller and softer in the last mentioned group than in the first.

Tachycardia was noticed in 65 per cent and 40 per cent, respectively. Fifty per cent of the patients in the first group and 60 per cent of those in the second group were complaining of anxiety, dyspnea, precordial pain, and other cardiac symptoms.

Excessive perspiration was reported by 52 per cent of the first group as contrasted to 42 per cent of the second group.

Hyperthermia was recorded in 8 per cent of the first group as contrasted to 3 per cent of the second.

While gastrointestinal disturbances were registered in only 8 per cent of the first group, they occurred in 20 per cent of the second group.

Considerable losses of weight beyond those that could be attributed to malnutrition were found in 45 per cent and 28 per cent, respectively.

Disturbances caused by food and vitamin deficiencies or poor quality of food, such as amenorrhea, dysmenorrhea, alopecia, and loss of libido, were noticed in 4 per cent of the first and 12 per cent of the second group.

A great frequency of chronic deforming arthritis, probably of neurotrophic origin, was found in both groups.

Tremor was recorded in 75 per cent of the first and 35 per cent of the second group.

JOSEPH K. NARAT, M.D.

The Treatment of Thyrotoxicosis D. M. DUNLOP *Edinburgh M. J.*, 1948, 55, 257

Dunlop observed 149 thyrotoxic patients. Of these, 19 were treated by thyroidectomy and the remainder were treated by antithyroidal drugs. Eighty-three were hospitalized, while 66 were treated as out-patients throughout. The author used 0.2 gm thiouracil three times a day.

Blood cholesterol and basal metabolism determinations were discarded early as criteria for the efficacy of treatment. Weight seemed to be a good means of judging. Tachycardia was slow to respond and occasionally persisted even after the basal metabolic rate had become normal. Auricular fibrillation reverted occasionally to normal rhythm but usually required quinidine for control. Innocent glycosuria was cured by thiouracil or thyroidectomy, severe diabetes frequently was ameliorated by either. Exophthalmus was unaffected by thiouracil, but lid retraction was more effectively influenced by thyroidectomy than by thiouracil.

Enlargement of the thyroid due to overstimulation by the thyrotropic hormone of the pituitary gland occurs when the patient is overdosed with thiouracil. Myxedema induced by thiouracil is temporary, but when it is induced by thyroidectomy it is permanent.

Sixteen patients (11%) showed toxic effects which led to abandonment of the drug in 6 (60%) of the

entire group or 56% of those who developed reactions. There was no mortality in this series, although a mortality of 0.5 per cent was reported in the older literature.

In order to avoid relapse, treatment should last a year or longer.

Nineteen, or 13 per cent, of the entire series of 149 patients were treated by thyroidectomy. The reasons were for the sake of appearance in large goiters and mechanical pressure signs. One patient had uncertain results, 7 patients had drug reactions, 2 were drug resistant, and 3 were persistent fibrillators.

Dunlop believes that the drug treatment is the treatment of choice in primary hyperthyroidism, recurrent goiters, and elderly patients, while thyroidectomy is preferable when the goiter is large or nodular, or there is resistance or sensitivity to the drug.

F. W. S. MODERN, M.D.

Cancer of the Larynx: A Statistical Study LE ROY A. SCHALL and JOHN J. AYASH *Ann. Otol. Rhinol.*, 1948, 57, 377

The authors followed up 418 cases of laryngeal cancer. Only 8 per cent occurred in females. The average age of the males was 60 years and that of the females 40 years. Tracheotomy was required in 80 cases, in 46 of these, it was preliminary and in 34 it was done during or shortly after irradiation. Two hundred and forty-six patients were treated by external irradiation. Carcinoma (grades 1 and 2) is more curable by surgery and irradiation. Limited lesions of grades 3 and 4 are best treated operatively followed by irradiation.

The success of external radiation depends on the site and extent of the lesion. The more localized the lesion is, the more radiosensitive it is, while cord lesions which have infiltrated the opposite side are radioresistant, and those beyond the confines of the larynx are nearly hopeless. Cancer arising from the false cords and epiglottis is radiosensitive, but becomes resistant if it infiltrates and fixes these structures.

Among 59 patients treated by laryngofissure only 39 were ideal cases, and even among these 10 developed recurrences. The recurrences developed mostly when the cancer passed the commissure. The nasal tube is inserted before anesthetization.

Ninety-seven patients were treated by laryngectomy with 4 operative deaths.

Closure without drainage seemed feasible.

Laryngectomy can still be done if external radiation fails, although healing may be delayed. The survival rate following laryngectomy for more than 5 years was 64 per cent.

In 19 cases of distant metastases 11 lesions were in the lung, 3 in the brain, 2 in the spine, and others were scattered.

Early rehabilitation of the patient by means of the esophageal voice is important.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS, CRANIAL NERVES

Hypertensive Syndromes Due to Craniovertebral Malformations Clinical, Radiologic, Neurosurgical Observations (Sindromi ipertensive da malformazioni cranio-vertebrali rilevi clinici, radiologici, neurochirurgici) G VERCELLI, F MASCHERPA, and G M TASTANI *Chirurgia*, 1948, 3 243

The authors report 3 cases which illustrate the value of surgical treatment for the correction of the serious disturbances of the nervous system caused by some malformations of the occipital bone and of the first cervical vertebra. The first patient presented a fusion of the atlas with the occipital bone, the second a malformation of the atlas and axis, and the third a typical example of basal impression in which the floor of the occipital fossa was convex and the external occipital protuberance in the horizontal plane passed through the mastoid apices. In the first and third patients the symptoms were caused, at least to a great extent, by blockage of the circulation of the cerebrospinal fluid which resulted in the formation of a ventricular hydrocephalus, while in the second patient the symptoms were the result of direct compression of the bulbomedullary tissues.

Experience has shown that the anatomic lesions at which surgical intervention must be aimed are essentially the following: (1) the decreased capacity of the cerebellar fossa due to upward displacement of the mass formed by the foramen magnum and the adjacent portions of the occipital bone, (2) the change in form of the foramen magnum, which is often greatly reduced in one of its diameters, (3) the changes in the dura mater which are modelled on the bone changes and are capable of exercising a compressive action even after removal of the bone malformation, (4) the changes in form and capacity of the upper opening of the spinal canal, which vary with the different types of vertebral malformations, (5) the adhesions which fix the cerebellum to the cerebral trunk and the medulla, and contribute to the compression of these structures and to the disturbance of the circulation of the cerebrospinal fluid, (6) the impaction of the cerebellar tonsils into the occipital foramen and the spinal canal, and (7) the hydrocephalus due to obstruction of the basal foramina as a result of the foregoing defects.

The surgical treatment must consequently be carried out in accordance with the following program: (1) removal of a more or less extensive portion of the occipital bone and of the posterior border of the foramen magnum, (2) removal of the posterior arch of the first and, if necessary, of the second and third cervical vertebrae, (3) ample opening of the dura mater, which should not be reconstructed, (4) liberation of the cerebellar tonsils, and (5) search for and section of adhesions between the cerebellum and the

cerebral trunk to allow free passage of the cerebrospinal fluid.

A special procedure had to be used in the third patient, in whom occipital and vertebral decompression and removal of the obstruction of the foramen of Magendie had resulted in disappearance of the subjective and objective symptoms, but after a few months the signs of intracranial hypertension reappeared because of renewal of the adhesions between the cerebellum and the cerebral trunk, and of the obstruction of the fourth ventricle. Under the circumstances a supraotic ventriculostomy was performed and led to definitive cure.

RICHARD KEMEL, M D

Delays and Errors in the Diagnosis of Brain Tumor

FREDERICK C REDLICH, REMBRANDT H DUNSMORE, and EUGENE B BRODY *N England J M*, 1948, 239 945

This brief article should have wide circulation and be read not only by psychiatrists and surgeons, but by neurologists, internists, and general practitioners as well.

The authors have emphasized how frequently the presence of brain tumors is overlooked in a cursory examination of the patient, and in their review of 100 consecutive proved cases of intracranial tumor they find that all too much importance is placed on the mechanical methods of diagnosis rather than the careful eliciting of history and the repeated (if necessary) careful neurological and physical examination. They stress the importance of a thorough investigation of the causes of physical impairment, of headache, and of epileptiform seizures.

It is admitted that functional and psychological factors may delay the complete diagnosis, and while public health education should be designed to avoid such delay, such education should be stressed at both lay and professional levels. JOHN MARTIN, M D

Transorbital Leucotomy WALTER FREEMAN *Lancet*, Lond., 1948, 2 371

Fiamberti is given credit for simplifying the operation of frontal leucotomy in 1937, which operation had been introduced by Moniz one year previously. On the basis of unpublished but previously reported work the author believes that transorbital leucotomy which undercuts areas 9 and 10 on the Brodmann Chart seems to be a valid procedure.

The operation, which it is claimed can be carried out by the properly trained psychiatrist, consists of the introduction of the leucotome under the upper eyelid, through the conjunctival sac, and across the orbital vault, where, with a slight hammer tap, it is driven through the orbital plate. No damage to the globe save occasional subscleral hemorrhage has been observed. The instrument is a tool steel shaft measuring 12 cm long and 4 mm wide tapering for the

last 6 cm. to a rather fine slightly beveled point. Proper maneuvers are described which serve to sever the fibers in the lower portion of the thalamofrontal radiation. The possibility of laceration of the arteries in the depths of the fissures on either the medial or lateral surface of the frontal lobe must be born in mind. Moderate pressure is maintained over the eyelids to prevent excessive orbital hemorrhage. Circumorbital ecchymosis persists for several days. The procedure is then repeated through the opposite orbit. It is advised that the postconvulsive phase of electroshock therapy is the time of choice for the operation. Recovery from the operation is said to be very rapid.

Complications have been observed in only 3 of 100 cases. In all of these there was bleeding with severe inertia, and paralysis in one and mild hemiparesis in the others. Undesirable personality changes are minimal. One-third of the schizophrenics and more than half of the individuals treated have been discharged from the hospital.

The operation is claimed to be most effective in certain patients in whom tension is a prominent feature of the illness and who are beginning to become chronic sufferers in spite of more conservative therapies. It finds its most successful application in patients who are benefited and then have a relapse or who are being carried on maintenance shock therapy. Severe emotional dilapidation is the outstanding contraindication.

ALLAN D. CALLOW, M D

PERIPHERAL NERVES

Clinical Assessment of Peripheral Nerve Injuries

W R HENDERSON *Lancet*, Lond., 1948, 2 801

This article is principally concerned with the value of Tinel's test in peripheral nerve injuries and is based on the author's experience with 400 cases observed in prisoner-of-war hospitals in Germany from 1940 to 1945. When it is interpreted according to its original description, Tinel's test is useful in assessing the amount of regeneration after about the fourth month following injury or suture of the nerve, provided it is interpreted by comparing sensations from the lesion and the distal segment.

The test fell into disrepute probably because too much emphasis had been placed on the sole presence or absence of response from the distal segment of the injured or sutured nerve. The author stresses the importance of palpation over the lesion as well as over the distal segment to perform and interpret the test correctly. It is believed that the test can be of value in assessing the prognosis of brachial plexus injuries after a few months, such as the traction injuries observed in parachute jumpers.

On the basis of Tinel's test, the author classifies nerve injuries into four clinical groups, assuming that sufficient time has elapsed to allow the fibers to regenerate at least several inches along the distal segment of the nerve. When no regeneration occurs, tapping at the site of the lesion elicits a strong re-

sponse with no response to palpation along the distal segment. A strong indication of a neuroma with negligible regeneration distally is shown by a strong response over the site of the lesion and a feeble response over the distal segment. Partial regeneration of a nerve is the most difficult type of lesion to interpret by Tinel's test. Complete regeneration will show a strong response of tingling along the distal segment advancing at the rate of about 3 inches a month. Also included in the article is a description of tests used to exclude damage to the nerves in recent injuries.

JOHN L. BELL, M D

MISCELLANEOUS

The Results of a Specifically Co-Ordinated Plan of Medical and Surgical Treatment of Essential Hypertension

LOYAL DAVIS, HOWARD A. LINDBERG, and N V TREGER. *Ann Surg*, 1948, 128 770

In 1934, Barker and Davis formulated a plan for the study of patients with essential hypertension for whom surgical therapy might be undertaken. In 1939, they reported upon their clinical and experimental experiences and attempted to make clear for others the principles upon which their work was being carried out, in the hope that eventually it would lend itself to comparison with that of other groups engaged in similar work.

The authors stress the point that before surgical procedures for hypertension can be evaluated, an agreement must be reached as to exactly which type of patient is being operated upon or should be operated upon. They studied some 700 patients with essential hypertension and attempted to classify them according to therapeutic and clinical types. Finally, they decided early to limit the surgical therapy to one of the types of essential hypertension and they chose that group for which medical treatment was inadequate and the progress of the disease appeared to be imminently fatal.

The first group of hypertension they termed the fluctuant group, the second, the plethoric, the third, menopausal hypertension, the fourth, the high diastolic type of hypertension, the fifth, arteriosclerotic hypertension, and the sixth, malignant hypertension.

Each of these particular groups are discussed and a case history is given for each group. The authors chose their surgical cases from the group of patients whom they classified as having the high diastolic type of hypertension. They further restricted their choice to those in this group who had been given an adequate and thorough trial of therapy with the thiocyanates and had proved to be resistant to this drug, that is to say, their diastolic and systolic pressures and their symptoms could not be improved by cyanate blood levels below those which produced toxic symptoms.

Another indication for the choice of patients was that they should have a labile blood pressure as evidenced by a group of pressor and depressor tests. General considerations upon which the surgical indications were based were that the patients should

stage 2 cases which present proved axillary metastases. The relative merits of preoperative and postoperative irradiation are difficult to evaluate since the statistics cited do not show the stages of the disease. However, it is stated that in 448 cases analyzed between 1930 and 1942, the survival rate with preoperative irradiation was greater than with postoperative treatment, namely, 73 per cent in the former and 53 per cent in the latter.

The over-all 5 year curability of 348 traced cases of all stages of cancer of the breast is 39 per cent, and varies from 87 per cent in stage 1 to 0 in stage 4.

FRANK B. QUEEN, M.D.

Surgical and Radiation Treatment of Cancer of the Breast ROLF BULL ENGELSTAD *Am J Roentg*, 1948, 60: 776

The author reports the results of a 5 to 10 year follow up study of 1,384 patients with cancer of the breast. Of these, 680 patients were followed for a period of 10 years. The plan of treatment is based on the stage of development of the disease.

Operable cancer of the breast with no clinical signs of pathologic spread is designated as stage 1. Treatment was surgical, with postoperative irradiation.

Operable cancer of the breast with clinically or histopathologically demonstrable operable metastases to the axillary and lymph nodes is defined as stage 2. Treatment was surgical, with postoperative irradiation, and ovarian irradiation with from 1,200 to 1,500 roentgens over two or three pelvic fields, followed by the administration of 100 mgm of testosterone propionate three times a week for a period of 10 weeks.

Inoperable cancer of the breast, or inoperable axillary or infraclavicular metastases or supraclavicular metastases, is defined as stage 3. Treatment in these cases was the same as that administered to patients in stage 2—roentgen irradiation, operation, and hormone therapy.

Inoperable tumor with distant metastases is defined as stage 4. These patients were treated with ovarian irradiation and testosterone injections.

Collective results including the four stages of cancer showed 520 of 1,377 patients (37.8%) to be symptom free after 5 years. The results obtained in the treatment of cancers in stages 1, 2 and 3 were found to be as follows: of 649 patients with operable and inoperable cancer, 498 (52.5%) were symptom-free after a period of 5 years.

Of the patients with stage 1 and stage 2 cancers, who were followed for 5 years, 55.6 per cent were symptom free following preoperative irradiation and radical operation, 66.7 per cent were symptom free after preoperative and postoperative irradiation plus radical operation, and 60.0 per cent were symptom-free after radical operation plus postoperative irradiation.

In the author's survey of a smaller group of patients who had been treated in later years, he observed still further improvement in results. Twenty-two patients who were operated upon, with post-

operative treatment, have been symptom free for a period of 5 years (constituting 86 per cent of patients with stage 1 and stage 2 cancers who were treated in later years). The author believes this method of treatment to be ideal for patients with stage 1 and stage 2 tumors.

The methods of radium and roentgen administration, as well as dosages, are discussed in detail.

JANE C. MACMILLAN, M.D.

TRACHEA, LUNGS, AND PLEURA

Rupture of Bronchus Due to External Chest Trauma, Report of 3 Cases with Recovery PAUL H. HOLINGER, ALBERT R. ZOISS, and KENNETH C. JOHNSTON *Laryngoscope*, 1948, 58: 817

Rupture of a bronchus is an unusual and serious complication of severe external trauma to the chest. Kinsella and Johnsrud presented a very complete review of the topic in a recent publication and were able to uncover only 38 cases in the literature. The first report of a patient surviving this type of injury was made by Krinitzki, in 1928. In this case, complete bronchial stenosis was noted as an incidental postmortem finding, the apparent result of chest trauma suffered 21 years previously. The second instance of recovery was reported in 1930 by Jones and Vinson, who were the first to establish the diagnosis clinically in a nonfatal case. Cases with recovery have since been reported with increasing frequency, testifying to the increasing awareness of the entity and also to the recent advances in the treatment of severe thoracic injuries.

Three cases with recovery are presented in detail to emphasize further the not too rare occurrence of traumatic bronchial rupture and to call attention to the complexities of treatment.

Bronchial rupture is a relatively rare complication of severe, nonpenetrating, external chest trauma. Patients who survive such major injuries are being clinically recognized with increasing frequency.

Traumatic bronchial rupture inevitably results in cicatricial bronchial stenosis. In the majority of cases this stenosis is complete.

A pathological sequela in cases with residual complete bronchial stenosis is a chronic atelectatic lung with reduction in respiratory capacity. Unique and noteworthy is the absence of complicating infection in most of these chronic atelectatic states.

Diagnosis in the intermediate and late clinical phases is dependent upon a history of severe chest trauma, the discovery of a persistent lung collapse, and the bronchoscopic and bronchographic findings of complete bronchial occlusion.

In the initial phase of bronchial rupture, treatment of the concomitant severe chest injury is the primary concern. The possibilities of early surgical repair of bronchial disruptions warrant further investigation.

In the management of old bronchial injuries one is handicapped by the lack of basic cardiopulmonary studies. Therapeutic pneumothorax and thoraco-

plasty are recommended under certain specified conditions. Resection is indicated in the rare case that develops complicating pulmonary infection.

JOHN E. KIRKPATRICK, M.D.

Traumatic Bronchial Rupture with Occlusion

PHILIP J. HODES, JULIAN JOHNSON, and JOSEPH P. ATKINS *Am J Roentlg*, 1948, 60 448

Bronchial tears are usually due to crushing chest injuries and are often fatal. When patients survive the injury, they may subsequently develop complete bronchial occlusion and pulmonary collapse. Thirty-two cases of bronchial tears have been recorded in the literature since 1889. Ten of these patients survived the immediate effects of injury and developed bronchial occlusion. In every instance the bronchial defect lay immediately adjacent to or within a few centimeters of the bifurcation of the trachea. Bronchial tears are attributed to two factors: (1) compression of the bronchus between the elastic chest wall and the rigid spine, and (2) abnormally high air pressures within the bronchus at the time of the impact, due to the inadvertent closing off of the larynx by the victim as he tries to protect himself from the onrushing blow.

The patients usually exhibit shock, dyspnea, anoxia, interstitial emphysema, and cough. Roentgenograms immediately after injury may reveal fractured ribs, interstitial emphysema, pneumothorax, pulmonary compression, and mediastinal shift. Therapy at this stage must be directed toward relieving the above signs and symptoms. If the patient survives, bronchial occlusion then begins to take place. Usually there exists a period of days or weeks between the date of injury and the time of complete bronchial occlusion by cicatrix formation. Bronchograms reveal a cup-shaped pouch at the site of occlusion. Therapeutic measures at this stage have included pneumothorax, occasionally helpful, and pneumonectomy, usually very helpful. Thoracoplasty has not been used to date. It is of interest that these collapsed lungs, removed at operation, show no evidence of infection in contrast to the usual atelectatic lung.

The authors report the case of a 36 year old man who had been violently injured and who developed complete bronchial occlusion of the right main stem bronchus with total collapse some 4 months after injury. A pneumonectomy was performed and the patient was completely relieved of his symptom of severe dyspnea.

JESSE E. THOMPSON, M.D.

Arteriovenous Fistula of the Lung Treated by Ligation of the Pulmonary Artery

GEORGE B. PACKARD and JAMES J. WARING *Arch Surg*, 1948, 56 725

The presence of arteriovenous fistula in the lung has been recognized clinically only during the past few years. The steadily increasing number of cases reported suggests that it is much more common than supposed. The stereotyped syndrome of cyanosis, clubbing of the nails, and polycythemia, without

abnormality of the heart, is accompanied by roentgenographic observations which are practically diagnostic.

The possible relationship of this condition to hereditary hemorrhagic telangiectasia is indicated, and the incidence of multiple lesions is emphasized.

Consideration is given to the distinctive features of the pulmonary circulation as compared with the systemic circulation, which may permit some variations in the treatment of pulmonary arteriovenous fistula as compared with treatment of fistula in the systemic circulation. Apparently arterial connection between the pulmonary artery and bronchial artery branches is hardly to be compared with the free collateral circulation existing in the systemic circulation.

Report is made of one of the early cases in which the condition was recognized and one of the early cases in which there was surgical treatment. It is known that many more cases, in which the condition has since been recognized and treated, are in the process of being reported. As far as we know, this is the only case in which the condition was treated, and, to date, beneficially, by simple ligation of the pulmonary artery.

JOHN J. MALONEY, M.D.

The Problem of the Solitary Lung Tumors

DONALD BRIAN EFFLER, BRIAN BLADES, and EDWARD MARKS *Surgery*, 1948, 24 917

Mass roentgenography has resulted in the discovery of an occasional solitary shadow, or spot, on an otherwise normal lung field. The diagnosis and management of these asymptomatic lesions may constitute a very real problem. In the past, observation has been the accepted procedure in the management of these patients. This has resulted in the assumption that the majority of these lesions were probably benign, otherwise the patient would have re-established contact with the physician.

With the continued improvement in surgical and anesthesia techniques, a definite changed attitude has been evolved. The authors review 24 cases in which a round pulmonary asymptomatic lesion was discovered through routine examination. Operation was advised for each of the 24 patients, at least for the purpose of biopsy. All consented and were subjected to thoracotomy. All of the lesions were considered benign neoplasms preoperatively. However, 15 per cent of the tumors proved to be malignant neoplasms after adequate tissue studies were performed. It is believed that this in itself justifies surgical exploration of every solitary tumor of the lung, even though the patient is symptom free and the lesion has every indication of being benign.

STEPHEN A. ZIEMAN, M.D.

Bronchial Carcinoma

R. C. BROCK *Brit M J*, 1948, 2 737

The improvement in operability of bronchial carcinoma is due largely to the fact that patients are seen early, rather than to improvement in the surgical technique. Operative technique is now largely

standardized Further improvement in curability is dependent upon earlier recognition of the signs and symptoms

The clinical features leading to the diagnosis of bronchial carcinoma are (1) an unexplained cough, (2) stained sputum, and (3) a vague deterioration of health, especially in elderly patients The most important step in early diagnosis is to think of the disease This is true particularly since lung carcinoma is a comparatively newcomer, and doctors trained 20 or more years ago were not brought up to be cancer-of-the-lung minded

The most important confirmatory procedures are roentgenography, bronchoscopy, and cytologic examination of the sputum (Cytologic examination of the mucus obtained at bronchoscopic examination has been found to yield accurate diagnoses in as many as 60 per cent of the cases in some clinics in the United States of America) Thoracotomy is the last logical examination and should be used when needed to establish the diagnosis as well as to assess the operability

The operation recommended is block-dissection pneumonectomy In this, the pericardial sac surrounding the hilar structure is removed with the lung, with complete block dissection of all the accessible mediastinal glands from the superior thoracic inlet down to the level of the diaphragm Lobectomy may be used in properly selected cases, i e, elderly patients with a peripheral type of growth in whom the hilum appears clear

In 666 cases seen from 1941 to 1947, the average operability was 11 per cent Operability has increased to 16.5 per cent during the past 3 years

In 101 operations, of which 15 were lobectomies, the operative mortality was 18 per cent (The collected operative mortality from 7 leading clinics in the United States and England varies from 15 to 32 per cent)

The 5 year survival rate thus far is 8 per cent, with 47 patients still alive and well for periods of from under 1 to 3 years

Twenty-eight patients have died since operation, 3 of causes other than recurrence It is believed that many of these obtained great benefit from operation since a number enjoyed a useful extra life span, and in many cases death came in a kinder form than would have been the case with an untreated tumor

HEART AND PERICARDIUM

Closure of Defects in Cardiac Septa GORDON MURRAY *Ann Surg*, 1948, 128 843

The cardiac septal defects present a challenge to the surgeon Attempts at closure, at least in part, have been carried out experimentally and in clinical patients and have resulted in moderate improvement.

In about 30 animals the authors passed sutures through in the line of the interauricular septum beginning at the site of the transverse sinus behind the

aorta, and coming out posteriorly between the superior vena cava and the right pulmonary veins With two, three, or four sutures passed through in this way, pulled taut, tied together posteriorly, and then tied anteriorly, it was possible to compress the anterior to the posterior wall of the auricle in such a way as to occlude the defect completely There was also the advantage of diminishing the size of the enlarged auricles On examinations of the specimens, the anterior wall of the auricles had healed to the posterior wall in such a way as to cause complete occlusion of the defect and construction of what appeared to be another interauricular septum

This would suggest further work which might go on to produce better effects anatomically and clinically The demonstration that this can be done with safety is probably the chief feature of the present work

JOHN J. MALONEY, M.D.

Surgery of the Heart B. NOLAND CARTER *J Am Med Ass*, 1948, 138 1207

The author describes the surgical treatment of several cardiac conditions Surgical therapy of heart disease in cases which have heretofore been considered hopeless is changing the prognosis

Acute suppurative pericarditis Penicillin and surgical drainage offer the best prognosis for this condition Early operation is important, and the most common approach is the anterior one Drainage tubes, irrigation, or both are used Chemotherapy has been disappointing The objections to pericardial paracentesis are (1) danger of injury to the heart, and (2) inadequate drainage

Chronic constrictive pericarditis Although medical treatment is often palliative, it is never curative While the inflammatory process is active surgery is unwise Technically, few changes have been made A portion of the thickened pericardium is removed by either the extrapleural or the intrapleural approach Early diagnosis is important because of atrophy from disuse and myocardial degeneration in long-standing cases

Coronary sclerosis The production of an adequate collateral circulation is the basis of surgical treatment in these cases Some methods are (1) scarification of opposing surfaces, (2) use of irritating substances (talc, asbestos, and acriflavine), (3) use of pectoral muscle flaps, and (4) anastomosis of the aorta to the coronary sinus with a transplanted vessel Pericoronary neurectomy has been used in an attempt to relieve anginal pain The author has modified the work of Lezius in using the lung as a source of blood supply The author points out the difficulty in evaluating clinical results because of the different methods used and the limited material

Nonpenetrating wounds of the heart Damage varies from actual rupture to mild contusion Signs and symptoms are frequently masked by evident injury to the bony thorax Findings are precordial pain, tachycardia, arrhythmia, dyspnea, and roentgenologic and electrocardiographic changes Surgical intervention is indicated (1) when a small rupture

of the artery occurs with hemorrhage and cardiac compression, (2) when there is cardiac compression from blood originating from sources other than rupture of the heart, and (3) when softening and fibrosis result in the formation of an aneurysm

Penetrating wounds of the heart Not all patients sustaining penetrating heart wounds need be subjected to operation (wounds from ice picks, small-bladed knives, and long pins) In larger wounds, surgery is indicated Aspiration is performed in selected cases only when the operating room is prepared for surgery

Retained foreign bodies The recent war has focused more attention on this subject Harken has pointed out that foreign bodies measuring 1 cm or more in two dimensions should be removed surgically Surgery is performed (1) to prevent embolism, (2) to diminish the danger of bacterial endocarditis, and (3) to decrease the incidence of myocardial damage

Patent ductus arteriosus Surgery in this field has served to limit complications of the condition and improve the prognosis in these cases Complete division of the ductus seems to be the procedure of choice It is pointed out that the operation has a curative value in the presence of subacute bacterial endarteritis, whereas at one time this complication was considered a contraindication

Coarctation of the aorta The most important sign is hypertension in the upper portion of the body with hypotension in the lower Additional signs are cardiac hypertrophy, scalloping of the ribs, absence of the aortic knob, and palpable pulsating arteries on the thoracic wall Resection on the coarcted portion with end-to-end suture is the treatment of choice

Tetralogy of Fallot A surgical attack is made for the relief of pulmonic stenosis, although each vessel arising from the aortic arch has been utilized for anastomosis Blalock prefers the innominate subclavian artery because of the better angle it makes when anastomosed The results in patients who survive have been phenomenal Side-to-side anastomosis between the aorta and either pulmonary artery has been used

ROBERT E. FLOER, M.D.

The Surgical treatment of Mitral Stenosis Valvuloplasty DWIGHT E. HARKEN, LAURENCE B. ELLIS, PAUL F. WARE, and LEONA R. NORMAN *N. England J. M.*, 1948, 239-801

Numerous complex physiologic and morphologic factors are concerned in the production of symptoms in patients with mitral stenosis

A preliminary classification is presented of patients incapacitated by mitral stenosis, who may be benefited by different types of surgery group A, patients with a low fixed cardiac output—mitral valvuloplasty, group B, patients with normal cardiac output—artificial interatrial shunt, and group C, patients with uncontrollable tachycardia or with anginal pain—cardiac denervation

Five operations have been performed Mitral valvuloplasty was performed in 2 patients of group A,

with 1 death Artificial interatrial defects were produced in 2 patients of group B, with survival in each case Denervation of the heart by bilateral removal of the inferior cervical and dorsal first to fourth ganglions in 1 patient of group C was followed by improvement

These cases are now reported only to indicate the ability of such patients to withstand operation The evaluation of any long term benefits attributable to these procedures—and, indeed, of the ultimate position of surgery in mitral stenosis—must rest on objective criteria gained from hemodynamic studies carried out before and after operation Subjective selection of patients and assessment of results lead to dangerous competitive exercises in surgical techniques rather than to advances in therapy

Four principles of the surgery of mitral stenosis have been evolved the operation should be performed without dislocation of the heart from the position of optimum function, the buttonhole opening of the stenotic mitral valve should be approached from the auricular side so that the funnel directs the cutting instrument toward the leaflet margin, surgical enlargement of the stenotic orifice should be so planned that there is a minimum burden from associated regurgitation (selective insufficiency) and maximum restoration of valvular function (valvuloplasty), and in the presence of mitral obstruction or regurgitation, undue acceleration of the heart rate must be prevented—tachycardia increases pulmonary vascular pressure and is associated with attacks of pulmonary edema and other forms of "pulmonary decompensation"

An unsuccessful attempt at producing "selective insufficiency" is presented It is suggested that tachycardia was an important factor in the disastrous outcome

A case report is presented of a patient with mitral stenosis who survived following an operation designed to produce "selective insufficiency" and "valvuloplasty" of the mitral valve

The need for more extensive and more effective valvuloplastic techniques is pointed out

JOHN J. MALONEY, M.D.

Chronic Constrictive Pericarditis A Study of 53 Cases PAUL OGLESBY, BENJAMIN CASTLEMAN, and PAUL D. WHITE *Am J. Sc.*, 1948, 216-361

The case histories of 53 patients with chronic constrictive pericarditis seen at the Massachusetts General Hospital, Boston, since 1914 are analyzed with respect to the clinical picture and the long term results of surgery Exertional dyspnea was the most common symptom and was followed in incidence by swelling of the ankles and legs, abdominal swelling, and abdominal discomfort The most common physical findings were, in order of their frequency, hepatomegaly, prominence of the neck veins, ascites, peripheral edema, and signs of fluid and/or pleural thickening at the lung bases

Cardiac enlargement as determined by roentgen films was present in slightly more than 50 per cent

of the cases, and by fluoroscopy the cardiac pulsations were found to be diminished or absent in 32 of the 40 patients so studied. Evidence of unilateral or bilateral hydrothorax and calcification of the pericardium were observed in about equal numbers, in slightly over 50 per cent of the cases.

Surgical exploration with pericardiolysis and partial pericardiectomy was undertaken in 42 patients, 5 of whom were operated upon twice because of failure of the first procedure to improve their clinical status satisfactorily. One patient has been operated upon 3 times. Fifteen of the 42 patients have been essentially cured of their symptoms by operation. There is unquestionable evidence that surgery benefited 10 other patients, 8 of whom are still living, while 2 died 6 years following pericardiectomy. Satisfactory or excellent results have thus been obtained in 60 per cent of the patients coming to operation. Of the remaining 16 patients, 6 died as a result of the operative procedure itself, 5 died from complicating diseases, and 4 died from the effects of their underlying disease.

The etiology was entirely obscure in 30 cases despite the fact that sections of the pericardium were available for microscopic study in 46 of the 53 cases in the series. Tuberculous involvement of the pericardium was proved in 9 patients. Healed fibrous scarring was the usual finding which may or may not have resulted from tuberculous infection.

From the pathological study of the autopsy material it is suggested that removal of the anterior or anterolateral portions of the pericardium alone may be inadequate to release auricular and ventricular action completely. Also, the friable and sometimes calcified nature of the myocardium may explain some of the poor operative results. The possibility has also arisen that the formation of scar tissue over the defect in the pericardium resulting from the partial pericardiectomy might reproduce the same constriction of the heart that was present prior to operation. Persistence of an active inflammatory process may also explain some of the poor surgical results.

ORVILLE F. GRIMES, M.D.

Constrictive Pericarditis with Obstruction of the Pulmonary Veins. WALTER LAWRENCE, JR., W. I. ADAMS and DONALD E. CASSIDY. *J. Thorac. Surg.*, 1948, 17: 832.

A case of chronic constrictive pericarditis followed from incipency to termination is reported, in which the cause for failure of surgical treatment was not disclosed until postmortem examination was performed.

In early 1946 a 14-year-old boy was admitted because of abdominal swelling, ankle edema and dyspnea. The diagnostic work up led to the opinion that his malady was produced by a mediastinal mass impinging upon and obstructing the pulmonary circulation. Such a mass was demonstrated by a chest roentgenogram.

At operation, considerable evidence of pleural and mediastinal inflammatory change of a chronic sort

was encountered, but a 2 by 2.5 inch tumor, classified as a cavernous hemangioma, was removed from the mediastinum in the region of the pulmonary conus. Immediate improvement was noted when the mass was removed. This improvement was short-lived, however, the venous pressure remaining elevated. Fluid persisted in recurring in the pleural and peritoneal cavities. Cardiac movements were restricted and fluid was aspirated from the pericardium.

Approximately 1 month after the first operation a decompression of the pericardium was carried out. This sac contained considerable hemorrhagic fluid, but no adhesions were recognized within the space.

Improvement was again noted, but 4 months later evidence of a constrictive pericarditis was present and an extensive decortication was performed. Little or no improvement followed this and the patient succumbed some days thereafter.

The autopsy revealed the failure of successful cardiac decompression to be due to cardiac failure induced by extreme cicatricial narrowing of the pulmonary veins.

The progressive character of an inflammatory lesion of the mediastinum nullified attempts at surgical release of cardiac constriction. The presence of a mediastinal tumor contributed to this result. Such a combination is unusual, of course, but it did permit this case of chronic constrictive pericarditis to be followed throughout its entire course. The constricting effect on the pulmonary veins was also a very unusual feature. The etiology of the inflammatory process could not be determined.

In 6 of 7 other patients with constrictive pericarditis who were treated, the results were satisfactory even though 2 required reoperation. In the seventh patient the condition was of tuberculous etiology and terminated fatally, this being the only case in which a definite etiology could be determined.

HIRSH T. LANCSTON, M.D.

Operation of a Stenosis of the Aortic Isthmus 6 cm in Length (Opération d'une sténose de l'isthme de l'aorte d'une longueur de 6 centimètres). J. BORRMA. *Presse méd.*, 1950, No. 39.

Congenital stenosis of the aortic isthmus presents a characteristic picture. There is marked hypertension in the aortic arch and its branches to the head and arms, causing frequent headaches and nausea. At the same time, there is hypotension and poor circulation in the lower half of the body. The patient complains of coldness in the legs, fatigue on walking, even intermittent claudication is observed. Pulsation is absent in the femoral and popliteal arteries.

The prognosis in patients not subjected to operation is poor. Most of them die during childhood or adolescence, either of rupture of the aorta or heart failure, or of cerebral hemorrhage. Even the majority of those who reach adulthood die before the age of 40. Because of the immobility of the aorta resection of the stenosis and end-to-end anastomosis is possible only if the stenosis does not surpass the length of 5 cm.

Fig 1 (Boerema)

In the first case a girl of 14 years, in whom the correct diagnosis was made soon after birth, complained of headache, nausea, chest pain, pain in the calves after walking, and dyspnea. The blood pressure in the arm was 150/105, there was no pulsation of the femoral and popliteal arteries, and the arteries of the foot could be demonstrated by oscillometric examination. Operation revealed stenosis of the isthmus of 6 centimeters' length. The left subclavian artery was very much dilated and appeared like a continuation of the aortic arch. As direct union of the aorta was impossible because of the length of the stenosis, the subclavian artery was ligated and, after resection of the stenosis, was joined to the descending aorta by end-to-end suture.

The operation was a complete success. Two weeks after surgery, the blood pressure in the arm was 135/90 and the pulse was present in the dorsalis pedis artery. The symptoms of headache, pain on walking, and the dyspnea had disappeared completely.

WERNER M. SOLMITZ, M.D.

The Surgical Treatment and the Physiopathology of Coarctation of the Aorta R. J. BING, J. C. HANDELSMAN, J. A. CAMPBELL, H. E. GRISWOLD, and ALFRED BLALOCK. *Ann Surg*, 1948, 128: 803.

Twenty-three patients with coarctation of the thoracic aorta were operated upon. Thirteen of the patients were 20 years of age or more, while 10 were younger. An anastomosis was completed in 21 cases of the 22 in which it was attempted. In 17 cases the stenosis was resected and an anastomosis of the proximal and distal ends of the aorta was performed. In 4 cases in which the proximal segment of the aorta

was too short for end-to-end suture, the left subclavian artery was used to by-pass the stenosis. There were 3 deaths in the series, including 1 in a child who had multiple congenital defects which had been recognized preoperatively.

Physiologic investigations disclosed no significant deviation of the cardiac output from normal. Blood flow through the arm, which was elevated before operation, fell during surgery. The blood flow through the leg rose postoperatively. Hypertension in the upper part of the body and hypotension in the legs were observed preoperatively. After operation, these pressures tended to equalize. Analysis of the physiologic data indicated no generalized elevation of peripheral vascular resistance. It is probable, therefore, that the hypertension in coarctation of the aorta is not attributable to a renal pressor mechanism, but is due to the resistance of the stenosis and collaterals.

JOHN J. MALONEY, M.D.

ESOPHAGUS AND MEDIASTINUM

Benign Stricture of the Esophagus EDWARD B. BENEDICT and RICHARD H. SWEET. *Gastroenterology*, 1948, 11: 618.

In an attempt to standardize the treatment of benign stricture of the esophagus, the authors have reviewed 60 cases of stricture. Clinically, all of the cases presented varying degrees of esophagitis, and many of the strictures were associated with other conditions, such as hiatus hernia, esophageal ulcer, and duodenal ulcer.

Once the differential diagnosis is established by roentgenography and biopsy examination has ruled

Fig 1 (Nissen) Sketch of the operative procedure. The denuded portion of the esophagus is covered by a pedicled flap of the upper segment of the lower lobe of the left lung.

out carcinoma of the esophagus (which is equally common in the older age group as is stricture) bougienage with dietary treatment was found to give satisfactory results in more than 60 per cent of the cases. Only if repeated bougienage fails is surgery indicated in the patient who is a good risk. Because of the inflammatory nature of the disease and the length of the stricture, plastic repair is difficult and unpromising. In most cases, therefore, the operation of choice is resection. JANE C. MACMILLAN, M.D.

Bridging of Esophageal Defect by Pedicled Flap of Lung Tissue RUDOLPH NISSEN *Ann Surg*, 1949, 129: 142

Grafts of lung tissue have been widely used for reinforcing sutures of the bronchial stump following lobectomy and pneumonectomy. In lobectomy, which is performed for benign lesions as a rule, preference is given to a pedicled flap. In pneumonectomy in which the high level of bronchus dissection does not permit preservation of a pedicled flap, Churchill was successful in securing bronchial closure with a free graft of lung tissue taken from the periphery of the excised lung.

A case history is given in detail in which a leiomyoma of the thoracic esophagus was removed and a pedicled flap of lung tissue was used to protect the critical area in exactly the same way as omental grafts are used in abdominal surgery. The illustrations show the technique of the procedure.

JOHN J. MALONEY, M.D.

Carcinoma of the Superior Mediastinal Segment of the Esophagus RICHARD H. SWEET *Surgery*, 1948, 24: 929

Up to the present time no satisfactory technique for the removal of a lesion located in the upper fourth

of the thoracic portion of the esophagus has been developed. Recently a modification of the technique used for the removal of tumors in the midthoracic segment of the esophagus has been proposed. Now, a growth situated in the superior mediastinal segment can be resected and a primary esophagogastric anastomosis with the short proximal esophageal stump can be made in the neck.

The technique involves dissection of the esophagus and mobilization of the stomach as the first phase of the procedure. The dissection is begun in the region of the tumor after the mediastinal pleura is incised above the aortic arch behind the left subclavian artery. If the tumor-bearing portion of the esophagus can be freed sufficiently to make it possible to perform a resection, the operation is continued by completing the dissection of the entire length of the esophagus within the thorax. The mobilization of the stomach is then accomplished and the integrity of the vascular arches along the lesser curvatures is preserved at all cost. The stomach is drawn into the left thoracic cavity behind the hilum of the lung and lateral to the aortic arch. Fixation is accomplished by a series of interrupted silk sutures. The diaphragm is sutured to the stomach just above the pylorus and the diaphragmatic incision is then closed.

The intracervical esophagogastric anastomosis is then accomplished as a second step in the procedure. The esophagus is pulled up from the mediastinum and out in front of the carotid sheath. The fundus of the stomach is brought forward medial to the apex of the lung and pulled up into the lower portion of the neck (Figs 1 and 2).

Here the anastomosis is done with careful approximation of the mucosa to mucosa and muscle edge to muscle.

Fig 1 (Sweet) Drawing to illustrate the method of bringing the fundus of the stomach from the apex of the left pleural cavity into the neck through an opening produced by resecting the medial half of the clavicle and of the first rib

The author reports a case, giving a detailed description of the method employed. The result was most encouraging. The patient was able to swallow normally and to eat a normal diet.

From the standpoint of long time survival, it is conceded that only the accumulation of experience and the use of the procedure in a large group of patients will prove its value. The probability of local recurrence is great because of the fact that the dissection must of necessity be carried out close to the diseased area. This fault, however, is characteristic of all resections of the esophagus except those near the cardia. It is contended that the relief from dysphagia and the assurance of the comfort of normal eating are benefits which can be expected in the majority of patients and make the procedure well worth the risk.

STEPHEN A. ZIEMAN, M.D.

Traumatic Chylothorax ROBERT R. BALDRIDGE and ROBERT V. LEWIS *Ann Surg*, 1948, 128: 1056

The actual mechanism of the development of chylothorax following injury to the thoracic duct is not clear, since anatomically the duct is extrapleural in position and chylothorax is an accumulation of chyle in the pleural cavity. Some believe that chyle can escape into the pleural cavity through an uninjured pleural layer, while others believe that a perforation of the pleura is always present, though unrecognized. Retropleural accumulations of chyle have been reported, and it is probable that the usual delay which occurs between injury and the development of chylothorax represents the time required for erosion of the contiguous pleura, and perforation of an enlarging chyloma into the pleural cavity.

Traumatic chylothorax is more common on the right than on the left side, except in cases of penetrat-

Fig 2 (Sweet) Drawing to show the relations of the stomach to the thoracic viscera and the structures in the base of the neck. Note (1) The stomach passes behind the hilum of the lung and extends forward in the apex of the left pleural cavity medial to the lung, (2) at the completion of the operation the anastomosis is on the posterior surface of the fundus of the stomach and lies anterior to the carotid artery and jugular vein.

ing injuries. As a general rule, injuries low in the thorax result in right chylothorax and high injuries in left chylothorax.

The immediate effects of chylothorax are mechanical in nature: (1) a time interval of 2 to 10 days, (2) sudden dyspnea, (3) shock, (4) rapid relief after thoracentesis, and (5) reaccumulation of fluid and recurrence of symptoms.

The secondary effects result from persistent loss of fluid, protein, fat, and lymphocytes: (1) loss of weight, (2) dehydration, (3) reduction in serum protein and body protein, (4) reduction in blood and tissue fat, (5) disappearance of lymphocytes and eosinophiles from the circulating blood, (6) inanition, oliguria, thirst, and (7) death.

The patient may live for a few days to a few months, depending upon the extent of the injury and the complications of the original trauma. The mortality rate approximates 50 per cent.

The accepted treatment of chylothorax has as its aims: (1) reduction of the volume of chyle, and the prevention of respiratory and vascular collapse from intrapleural pressure, (2) maintenance of nutrition, and (3) measures designed to favor healing of the duct, but none of the measures hitherto used is eminently successful.

It has been abundantly demonstrated that the integrity of the thoracic duct is not essential to life. When a patient with an injured duct presents a progressive downhill course, therefore, and conservative methods fail, surgical ligation of the duct would appear to be the only logical therapeutic procedure.

A case of injury of the cisterna chyli during sympathectomy for hypertension, with cure of the resulting chylothorax by ligation of the thoracic duct, the cisterna chyli, and all of its main afferent trunks, is described. Lymphaticovenous anastomoses within the abdomen are adequate for the return flow of lymph and chyle following obliteration of the cisterna chyli and the lower thoracic duct.

When indicated, ligation of the thoracic duct or cisterna chyli, or both, is feasible, and may in some cases be a life saving procedure.

MISCELLANEOUS

Strangulating Diaphragmatic Hernia of the Liver

SAMUEL A. WOLFSON and ALFRED GOLDMAN *Surgery*, 1948, 24: 846

A case of congenital, strangulated, diaphragmatic hernia of the liver with surgical cure is reported. This case included a unique symptomatology of attacks of nausea, vomiting, and epigastric pain described as "cloudlike" with radiation to both lower, lateral thoracic areas. A "doorstep" feeling on bending forward was a prominent feature of the symptomatology. These symptoms probably have a causal relationship to the strangulation of the herniated liver, and with the surgical reduction of the hernia the patient experienced both a complete and lasting cure.

When a mass is demonstrated roentgenologically in the pericardiophrenic sulcus, herniation of the liver should be considered as well as the more common lesions. If abdominal symptoms of the type described are present, it is reasonable to suspect strangulation of the herniated liver, and exploratory thoracotomy should be advised.

JOHN J. MALONEY, M D

Thoracoabdominal Approach for Portacaval Anastomosis

VICTOR P. SATINSKY *Ann Surg*, 1948, 128: 938

The work of Whipple, Blakemore, and Lord has established portacaval shunt as an effective means of treating portal hypertension in properly selected cases. In general, a portacaval anastomosis is more desirable than a splenorenal anastomosis because of the larger size of the shunt in the former. In many cases, however, splenorenal anastomoses have been done because of the technical difficulties encountered in performing the portacaval shunt.

A new right-sided transthoracic, thoracoabdominal approach is described in which either the eighth or the ninth rib is resected, the diaphragm divided, the abdomen opened, and the liver dislocated into the right hemithorax. Access to the structures in the gastrohepatic omentum and to the hilum of the liver is simplified, enabling a high ligation of the branches of the portal vein from its lateral aspect and thus affording a longer segment of vein for anastomosis to the vena cava. Exposure is wide and all structures are presented more superficially than when the patient is on his back. Postoperative ileus is reduced to a minimum and little chance for postoperative incisional hernia exists.

Experiments on 6 dogs were carried out as a preliminary step, and a 45 year old male patient with cirrhosis of the liver then had a portacaval anastomosis successfully performed by this approach, using a one layer Blalock type of intima-to-intima suture with No. 5-0 braided silk. Heparin was not used postoperatively.

The suggestion is made that this route be used in the performance of reconstructive surgery of the common duct in cases in which the injury is close to the hilum of the liver, and for operations on the right adrenal gland.

JESSE E. THOMPSON, M D

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Abdominal Wound Closure in the Substandard Patient MILTON W DURHAM and JOEL W BAKER
Bull. Mason Clinic, 1947, 1 4

A new technique of abdominal wound closure is described which has been found to be especially beneficial in certain groups of patients, including (1) those with disturbed healing capacity (as attested by a lowered serum protein value or a reversal of the A-G ratio), anemia, or reduced blood volume and reduced vitamin values, (2) those with wounds which are actually or potentially infected, and (3) those with wounds made through previous incision scars. Chronically debilitated patients, those with malignancy, weight loss, and impaired hepatic or renal function, patients with peptic ulcer (particularly those with obstruction), and all those with intestinal anastomoses, including gastric and colon resections, require special attention to wound closure, to forestall disruption or postoperative hernia.

Particular advantages of the technique include the minimal reaction to the steel sutures which allows them to remain a considerable length of time with negligible skin reaction, and broad splinting of the wound which allows immobilization of the part but early ambulation of the patient. Closure of abdominal wounds of the type described was performed in 100 consecutive cases following, for the greater part, colon and gastric resections, without wound disruption or postoperative hernia. As a rule the technique is accomplished on paramedian rectus retracting incisions with the peritoneum and posterior rectus sheath in the upper abdomen, or the peritoneum alone in the lower abdomen, with a running suture of 0 or 00 chromic catgut, since a continuous suture results in a smoother intra-abdominal wound and allows less space between sutures through which a hernia might develop.

The remaining closure is carried out as shown in Figure 1, with No. 30 steel sutures which are allowed to remain in place 21 days, and up to 35 days on occasion, according to the degree of healing. The final result with the sutures tied and demonstrating a strong wound support is shown in Figure 2. The sutures are easily removed by cutting the steel on the side opposite the knot next to the skin and pulling the knot with a hemostat.

The Costal Arch Resection. A Substitute for the Transthoracic Approach to Upper Abdominal Pathology L P GAMBEE and ANTHONY INGALA
West J. Surg., 1948, 56 605

The authors believe that requisite exposure of viscera lying high in the abdomen can be obtained via an abdominal incision without extension into the thorax. The incision which has been developed and offered to supplant the combined abdominothoracic

Fig 1

Fig 2

Fig 1 (Durham, Baker) Strand A sutured through the anterior rectus sheath with Mayo needle 0.5 cm from the edge of the rectus sheath strand B sutured through skin from 2.5 to 3.0 cm from the skin edge, then matted back through both skin margins 0.3 cm from the incisional margin with large curved cutting needle and back through the skin margin to become strand C. The sutures are placed 1 cm apart and then tied over rolls of gauze 2.5 cm in diameter and the same length as the incision.

Fig 2 Cross section of the incision after suture is snugly tied over the roll of gauze. A thin gauze dressing is then placed over the wound and the wound is sealed with vertical strips of wide adhesive tape.

approach is one transecting the recti and augmented by its extension over the costal arch and excision of the arch. The incision is physiological in that motor innervation is preserved and that the incision parallels the lines of abdominal stress. Exposure has been consistently abundant and has expedited the accomplishment of the primary surgical objective, thereby offsetting the added minutes consumed in opening and closing this incision. Closure has been completed easily without tension, with the patient slightly jack-knifed. Healing has been most satisfactory and postoperative complications few.

JOHN J. MALONEY, M.D.

GASTROINTESTINAL TRACT

Intraperitoneal Injury of Hollow Viscera Due to Nonpenetrating Wounds CHARLES A. REIF-SCHNEIDER and ERWIN R. JENNINGS *South M J* 1948, 41 888

Intra-abdominal trauma presents one of the most difficult problems with which a surgeon has to deal. Injuries to the hollow viscera may be caused by penetrating wounds or may be due to nonpenetrating injuries from blunt force. Of the two, the latter variety offers more difficult problems in diagnosis. The trauma to the hollow viscus may act in different ways. A severe blow may rupture any portion of the gastrointestinal tract. If the intestines are ruptured, the tear is most likely to occur near the ligament of Treitz or near the ileocecal junction. The intestine may be torn from its mesentery, may be crushed between the abdominal wall and the spinal column, or may be punctured by a spicule of bone from a fracture of the pelvis.

When a patient with a suspected intra-abdominal injury is admitted to the hospital, he should be watched very carefully. If possible an accurate history should be obtained, especially of the time of the accident, and the character and force of the blow. He should be carefully examined, and his pulse, temperature, respiration, and blood pressure should be recorded every 15 minutes. A specimen of urine should be obtained. If he cannot void he should be catheterized. The urine should be examined for macroscopic and microscopic blood. A rectal examination should also be made. He should be typed immediately for transfusion. If possible a flat x-ray plate of the abdomen should be made, as air under the diaphragm may clinch the diagnosis. A blood count and hematocrit determination should be made. The degree of rigidity of the abdominal muscles should be carefully noted, as well as the percussion note, to determine whether or not there is any free fluid in the peritoneal cavity.

If the pulse rate increases and the blood pressure falls, it usually means active hemorrhage and immediate laparotomy is justified. If the patient gives a history of injury to his abdomen, he should be kept under observation for at least 6 hours. This is just as important as the period of observation given to head injuries. A patient should not be discharged from the accident department while still complaining of abdominal pain.

Nonpenetrating rupture of the stomach is rather uncommon. There are no distinctive symptoms or signs of gastric rupture. Excruciating pain is present if the gastric contents are spilled into the peritoneal cavity. This is accompanied by marked tenderness and boardlike rigidity of the upper abdomen. Nausea and vomiting are usually present. The vomitus may or may not contain blood. Symptoms of shock appear early. A flat roentgenogram of the abdomen may show air under the diaphragm.

Rupture of the small intestines due to a nonpenetrating wound is usually single, but it may be

multiple. It is most likely to occur at or near one of the fixed points, such as the ligament of Treitz or the ileocecal junction.

Early diagnosis is of great importance. If the operation is delayed more than 6 hours the patient's chance of recovery is greatly decreased. If 12 or more hours have elapsed between the accident and the operation, the prognosis is very bad. If the operation is delayed 24 hours or more, the result is usually fatal.

The patient should be treated for shock with plasma, given intravenously. He should be immediately typed for transfusion. The choice of anesthetic is most important. Spinal anesthesia is contraindicated. If the injury is complicated by intrathoracic trauma, the anesthetic setup must be adequate.

The abdomen is usually opened through a right rectus incision. If free blood is found in the peritoneal cavity, the site of injury should be quickly located and the hemorrhage controlled. It should be noted whether any gastric or intestinal contents are mixed with the blood. The spleen and liver should be quickly examined for laceration.

Local suture, instead of an anastomosing operation or resection, should always be done when possible. If a wound in the intestines is repaired, the line of suture should be transverse to the long axis so as to diminish the chance of constriction of the lumen.

It is a known fact that mortality is greatly increased in resection. According to Bailey, resection should be done only (1) when a section of the intestine has been destroyed, (2) when there are several large perforations within a short distance of one another, and (3) when injuries affecting the mesentery and its vessel endanger the circulation of the intestines.

The existence of traumatic appendicitis is still extremely controversial. In order to make a definite diagnosis of traumatic appendicitis, it would be necessary to find evidence of trauma of the appendix following a blow of the abdomen, such as laceration or hemorrhage of the walls of the appendix or of the mesentery of the appendix. McCarthy and Magrath, of Philadelphia, reported 2 cases of traumatic appendicitis. In 1 case the appendix and appendical mesentery were detached from the cecum. In the other the appendix was detached at its base.

In 1939, Connell, of Denver, in answer to a questionnaire, tabulated 49,604 cases of acute appendicitis. In this series there was a history of trauma in 11 cases only. In 1 case a pin was found in the appendix, in another there was intussusception without internal violence. If these 2 were eliminated, the remaining 9 cases would give a percentage of 0.0018 in which trauma was mentioned as an etiologic factor.

Rupture of the large intestines due to a blunt blow is rather rare. The large bowel may be ruptured by a sharp fragment of bone from a fracture of the pelvis or may be torn when air is forced into the rectum by a hose.

A full bladder extends above the symphysis pubis and may be injured by a blow to the lower abdomen. Fracture of the pelvis is not infrequently complicated by a rupture of the bladder. The rupture may be extraperitoneal or intraperitoneal, the latter condition being much more serious. If the intraperitoneal rupture is not recognized and operation is not performed early, a fulminating peritonitis is found. If the rupture is extraperitoneal, marked urinary extravasation may take place.

Physiologic salt solution should be given with great care until the peritonitis is well controlled and normal gastrointestinal function has returned. The administration of salt results in the collection of the sodium at the sites of trauma in the body, which are principally the operative site and the bowel wall. This results in edema at the operative site, and large collections of fluid within the bowel lumen. An excess of saline in the body is exaggerated by the stimulated adrenal glands and results in the retention of sodium. Sodium excess is also accentuated by the usual partial disturbance of kidney efficiency. It must be remembered that blood and plasma contain salt equaling approximately 9 gm per liter. Thus, adequate daily salt intake, usually considered between 4 and 9 gm, is administered in these agents. Further salt, if needed, may be given.

The use of antibiotics in a diffuse peritonitis due to a perforated viscus is directed toward control of the infectious process often caused by many different organisms which are present.

JOHN E. KIRKPATRICK, M.D.

Gastric Ulcer. A Study of 600 Cases. FRANCES H. SMITH and SARA M. JORDAN. *Gastroenterology*, 1948, 11: 575.

The authors review 600 cases of gastric ulcer, 59 of which were found to be malignant histologically, 12 ulcers were found to be malignant clinically but were not operated upon. They divide these cases into 3 categories: (1) malignant ulcers, (2) benign ulcers which were operated upon, and (3) benign ulcers which were not operated upon, and then they compare the findings in the benign and malignant groups.

The incidence of malignant ulcers was found to be 9.8 per cent, or 59 cases; these were proved histologically. Of these, 54.7 per cent were operated upon within 2 months from the time they were first seen at the Lahey Clinic. Refusal of operation and delayed hospitalization (and the lack of x-ray evidence in 1 case) accounted for delay in operation of from 2 to 4 months. Of 5 patients on whom operation was delayed from 4 to 6 months, 1 did not return for 4 months and 4 had persistence or recurrence of symptoms although the roentgen signs had disappeared. The 10 patients operated upon later than 6 months had had medical treatment in or out of the hospital and were operated upon because of recurrence. Of the 59 ulcers found to be malignant, 33 were resectable. The survival chart for these cases is shown in the following table.

TABLE I — 600 CASES OF GASTRIC ULCER

Analysis of 44 Operated Malignant Ulcers
Survival Period of 33 Resectable Cases

Duration	Cases	
	Number	Per cent
2 years postoperatively	19	57.5
5 years postoperatively*	5	15.1

*1 patient was alive and well nine years after operation for lymphosarcoma.

There were 211 cases of benign gastric ulcers in which operation was done. Three patients were subjected to total gastrectomy and 208 to partial gastrectomy. Table II shows a summary of the indications for operation in these cases.

It should be noted that while some of these patients underwent resection at intervals varying from 2 months to 11.5 years after coming to the Clinic, 66.8 per cent of them were operated on within 2 months after they were first seen at the Lahey Clinic. Of the 211 operated on, 10 died before leaving the hospital, 5, or 2.4 per cent, may be considered to have died as the direct result of the operation, including bronchopneumonia in 1932, peritonitis in 1933, pulmonary embolus in 1935 and 1945, and cachexia in 1936. Table III is an analysis of the postoperative results for 5 years after gastric resection for benign ulcer in 211 cases.

The medically managed ulcers, or those not treated surgically, make up the third category and include 332 patients. There were 2 patients with malignant ulcer (proved by postmortem examination 6 and 23 years after the patients were first seen at the Lahey Clinic), 41 patients could not be followed up, and there were 15 deaths among the 104 cases followed up for less than 2 years. Four of these 15 deaths were due to hemorrhage and 11 were due to other nonrelated coexisting conditions. The cases of recurrence were studied and the recurrences were

Fig 1 (Smith, Jordan) The incidence of malignancy in various locations

attributed largely to dietary indiscretions, and emotional upset or worry

In comparing the malignant and benign groups it was found that anacidity occurred twice as commonly in the former as in the latter group, but it was observed that hyperacidity is not incompatible with gastric malignancy. Marked weight loss occurs in a much greater percentage of the benign cases than of the malignant ones. The incidence of hemorrhage and obstruction is similar in the two groups, and perforation occurred twice as often in the benign as in the malignant ulcers. The number of cases of coexisting cholelithiasis approximate an incidence identical with that in the general population. The finding of an hourglass stomach in patients with gastric ulcer is interesting because of the preponderance in the malignant group. X-ray deformity of the duodenum is comparable in the benign and ma-

*Hypochromic or normochromic mild in all cases

lignant groups. Symptoms were similar in both types, except that the patients with benign ulcer tended to have more night pain, and nausea in greater incidence, than those with malignant ulcers.

Gastroscopy was found not at all helpful for diagnosis in 25 per cent of the cases, and in 4.3 per cent of 93 cases a false negative or "benign" impression was obtained on visualization. This is partially accounted for by the high occurrence rate of malignant lesions in spots blind to gastroscopy, as shown on the accompanying diagram.

It should be noted that while the usually estimated incidence of malignant degeneration of an ulcer is 10 per cent, there were only 2 cases in this series known to have become malignant. Assuming that the 4 (follow-up) deaths in the same group were due to cancerous change, the maximum incidence of malignant degeneration was only 5.4 per cent in this series. Even this compares favorably with the hospital mortality of 4.7 per cent and the operative mortality of 2.4 per cent.

There were 20 cases (constituting 3.3 per cent of the total) in which the patient was mistakenly treated for a benign ulcer, and when he was operated upon for recurrence of symptoms a malignancy was found. It is not proved that these ulcers did not degenerate into malignancies during medical treatment, as they well may have done. It is the feeling of the authors that this may have happened in this group in which surgical treatment was delayed. The resection of all recurrent ulcers is advocated even though the resection of some benign ulcers will result.

The criteria of healing ulcers are discussed and evaluated in this paper as follows: the progress of healing (as judged by means of x rays), the subsidence of the symptoms, and the disappearance of occult blood in the stools, which should all be observed in 3 or 4 weeks, and be complete in from 6 to 8 weeks. Unless the patient follows the medical regimen, and the healing signs are satisfactory, it is believed safer to resect the ulcer early.

JANE C. MACMILLAN, M.D.

Subcardiac Gastric Ulcer (*L'ulcera gastrica subcardiale*) A. CIMINATA *Gior ital chir*, 1948 4 443

According to the author, who has performed about 1,500 operations on the stomach, 15 per cent of stomach ulcers occur in the subcardiac area. In these cases he doubts the rationale of doing a gastric resection when a simple gastroenterostomy, with its lower mortality, may be sufficient.

In subcardiac ulcer the advisability of doing a gastric resection depends on the amount of gastric tissue available to insure satisfactory suturing. Therefore the extension of a subcardiac ulcer to the esophagus prohibits a resection. When the ulcer involves the posterior wall of the stomach and penetrates the pancreas, the information as to the amount of gastric tissue available for suturing is obtained by passing the ulcer. When the author is unable to do so, he follows the advice of Finsterer, i.e., he

performs a gastrostomy, inserts the finger in the stomach, and proceeds to explore the stomach up to the esophagus, thus also obtaining information as to the size of the ulcer

He advises that enterostats be discarded when a gastric resection is done, a suggestion made first by Tansini in 1923, he stresses the meticulous ligation of the submucous vessels to prevent dehiscence of the sutures and advises ligation of the gastric artery where it courses downward to prevent ischemia of the critical part of the resection. By following this technique he lost only 1 case among the 35 resections he performed for subcardiac ulcer because of dehiscence of the sutures

The step type of resection is the best one in these cases because it allows resection of the small curvature up to the cardia and removal of the pyloric end which is the ulcer-genetic factor

JOSEPH M. A. PAPE, M.D.

Gastrojejunal Ulceration A. G. R. LOWDON *Edinburgh M. J.*, 1948, 55 533

Gastrojejunal ulceration is of peculiar interest and importance for several reasons. It is a man-made disease, a failure of the surgical treatment of ulcer, moreover, it is a serious failure because it is frequently a more troublesome and dangerous condition to the patient than the original complaint. It carries with it the risk of the usual complications of peptic ulcer—hemorrhage and perforation—and, in addition, other complications equally as serious, if not more so. The surgical treatment of gastrojejunal ulcer, often imperative, is difficult and dangerous.

If cases are carefully selected as suitable for the operation of gastroenterostomy, the incidence of gastrojejunal ulcer should be less than 3 per cent. If gastroenterostomy is performed for all cases of duodenal ulcer, irrespective of sex, age, or the degree of stenosis or hyperacidity, the incidence of gastrojejunal ulcer will be 20 per cent or more. The incidence of gastrojejunal ulcer after partial gastrectomy is under 2 per cent.

Preventive treatment of gastrojejunal ulcer must consist primarily in the careful selection of cases for the operation of gastrojejunostomy. It is probably wise to avoid the operation in any patient under 45 years of age unless there are contraindications to the more formidable procedure of partial gastrectomy, and to confine its use to patients in whom the peptic ulcer is associated with some degree of pyloric stenosis and a normal or low acid curve.

Partial gastrectomy has been proved by experience to be a satisfactory treatment of gastrojejunal ulceration. In practice it produces a high percentage of cures. The operative mortality of partial gastrectomy for anastomotic ulcer has, however, been unfortunately high.

Vagotomy is now under trial as an alternative method of reducing the hydrochloric acid secretion. The immediate results of the operation are very gratifying, there is complete relief of ulcer pain and a marked fall in acidity. It is still too early to judge

the lasting value of the procedure, but it can, on present evidence, be regarded as the treatment of choice for anastomotic ulcer in elderly or bad risk patients and in all cases of recurrent ulcer after partial gastrectomy.

There are a number of important complications associated with gastrojejunal ulceration. An abscess may develop in the anterior abdominal wall, but this is now rarely seen because the anterior anastomosis is seldom performed. Free perforation into the peritoneal cavity is comparatively common, it occurred in 18 of the 67 patients. It may occur repeatedly. Perforation is usually to be taken as an indication to treat the patient by gastrectomy as soon as he has recovered sufficiently from the primary operation for closure.

Hemorrhage from a gastrojejunal ulcer presents considerable difficulty both in diagnosis and in treatment. The diagnostic problem is to decide whether the hemorrhage is from a stomal ulcer or from a recrudescence of the primary ulcer. Fortunately, hemorrhage from a secondary ulcer is seldom so severe or persistent as it may be when a posterior duodenal ulcer erodes a branch of the gastroduodenal artery.

Gastrojejunal fistula is one of the most difficult problems that can confront an abdominal surgeon. The symptoms are very characteristic—diarrhea, vomiting of fecal material, belching of foul gas, and progressive wasting. Pain is frequently absent, or slight.

CHARLES BARON, M.D.

Partial Gastrectomy for Peptic Ulcer H. W. PORTER *Edinburgh M. J.*, 1948, 55 549

While the final answer to the treatment of chronic peptic ulceration will almost certainly be found in the sphere of the physician, there is at present a considerable proportion of patients who can obtain no permanent alleviation of symptoms from medical treatment, and the majority of these can be greatly benefited, if not completely relieved, by the surgeon.

The disadvantages of partial gastrectomy may be tabulated under the following headings: the operative mortality, anastomotic ulcer, inability to return to normal diet, postoperative dumping syndrome, anemia, inability to return to former employment.

An analysis was made of 118 unselected cases (87 duodenal, 20 gastric, and 11 stomal ulcers).

The indications for operation were repeated perforations (38 cases), hemorrhage (17 cases), and failure to respond to medical treatment (63 cases). Patients who failed to respond were those who had had more than one adequate course of medical treatment in the hospital and were not benefited, or had had a recurrence in spite of adherence to medical treatment after discharge, and (b) people who were unable to continue adequate medical treatment due either to economic factors or low intelligence.

There were 4 deaths, all of which occurred in patients in the 50 to 60 year age group, which may be an argument for instituting surgical treatment at an earlier date.

The postoperative complications were pulmonary atelectasis in 22 patients, hemorrhage in 7, pulmonary embolus in 1, pneumothorax in 1, obstruction at the stoma in 1, and bowel obstruction in 1, leakage from the duodenal stump did not occur in any of the cases. Several factors contributed to a satisfactory recovery. Prophylactically, they were (a) the abolition of constricting abdominal binders and dressings, (b) early rising to encourage abdominal breathing, (c) the avoidance of indiscriminate use of gastric suction, (d) encouragement to cough, which not only entails reassuring the patient regarding the ability of his wound to stand the strain of coughing, but may also necessitate personal supervision to make sure that he does cough, (e) the avoidance of respiratory depressant drugs as far as possible, especially morphia (the use of procaine intravenously may prove to be a suitable substitute), (f) the avoidance of postoperative dehydration. In the treatment of collapse, should it occur the use of penicillin has proved invaluable.

It has been possible to follow up all patients who were operated upon. Three patients have died since their discharge. In 1 of these a gastrojejunocolic fistula developed, in 1, an acute lobar pneumonia developed 6 months later, the third patient had two attacks of acute obstructive jaundice 4 months later and after exploration, which revealed no stone, the jaundice cleared up, but the patient had a flare up of quiescent pulmonary tuberculosis which proved fatal. All of the remaining patients are alive and well. All but 2 of these have returned to their former employment (84 per cent of these returned in 3 months or under, and 24 per cent returned in 6 weeks or under). Several among the 24 per cent were able to undertake heavy manual work.

Many authors believe that gastrectomy is but one step in the treatment of peptic ulcer, and that it is necessary for patients to continue on a strict ulcer regime after operation. This may be due in part to the fact that the majority of patients who have undergone a large or full length anastomosis cannot eat a full meal. It has been shown that the gastric remnant remains small for a long period after operation—18 months or more—and that after eating there is gross jejunal bulging. One cannot help feeling that any major operative procedure directed at curing the patient must be regarded as a failure unless he can consume a full normal diet and lead a normal life. In this series, no case followed up roentgenologically showed gross jejunal bulging and all showed dilatation of the gastric remnant to 3 or 4 times its original size within 6 weeks of operation. This has enabled 99 per cent of patients to return to a full diet—normal in quantity and quality—within a period of 6 weeks. It is obvious that the psychological effect of being able to eat anything and everything is very great. Finally, the answer to the last question in the follow-up. Would you advise a close relative to have this operation under similar circumstances? Approximately 90 per cent of the operative

(CLAUDE J. BARKER, M.D.)

"Palliative Gastrectomy" in Cases of Duodenal Ulcer

IVAR SPAR, *Acta Chir Scand* 1945 97 9

The author uses the term "palliative gastrectomy" to describe the operative procedure for duodenal ulcer when the ulcer is left in situ but the procedure is otherwise similar to a Billroth II operation. It is the procedure which is more commonly described in the American literature under the term of the Finster exclusion operation. The article is based on a comparison of the results of 83 "palliative gastrectomies" with those of 102 radical Billroth II resections with complete removal of the ulcer, the two series comprising all of the cases of duodenal ulcer operated on in the years from 1936 to 1945 with a follow up of at least 1 year.

"Palliative gastrectomy" was performed on all patients with an ulcer penetrating into the pancreas when injury to the pancreas or the gall ducts might be entailed by radical operation. The author emphasizes that a palliative resection must be systematically planned and that when it is resorted to in an emergency after radical excision has proved impossible, irreparable damage to the blood supply of the pylorus has usually taken place which will result in serious and often fatal leakage from the pyloric stump. In performing this operation the author excises the mucosa of the pyloric stump and invaginates the remaining tissue, taking care to be sufficiently proximal to the pylorus to allow easy invagination.

The comparison of the results in these two large series is of great interest. The mortality for palliative resections was 2 per cent and for the radical operation 5.5 per cent. In the follow up 91 per cent of the patients who had had a "palliative resection" had a satisfactory result, while 80 per cent of those on whom the complete operation with excision of the ulcer had been performed had satisfactory results. In studying the patients postoperatively the author found no significant difference in the production of acid in the two groups, nor was there any difference in the incidence or severity of postoperative dyspeptic symptoms. In both groups some patients had, in addition, an enteronastomosis, but no difference in the postoperative course could be found.

The author thus concludes that there is no significant difference between the effects of the two methods of operation, and as the palliative resection in many cases has a lower mortality it should be widely used.

I. J. THOMAS, JR., M.D.

Gastric Polyps

LEO J. HARTZ, LEONIDEX S. SHAM, and GEORGE MILLS, *Gastroenterology* 1944 11 69

The authors present 6 cases of gastric polyps. The highest incidence occurred in the first 3 groups, 70 per cent of the patients in the first group and 50 per cent of the second. Of the 6 patients 75 per cent were males and 25 per cent were females.

Gastric cancer may develop in the polypoid gastric mucosal wrappings, but this is not a

SURGERY OF THE ABDOMEN

findings, often reveals some type of polypoid growth. These growths have, at times, no definite characteristic criteria as to their malignant or benign nature. Most of them, regardless of the later proved diagnosis, had no free acidity on the test meal, and most of them had a normal mucosa, so that deviation from the normal in such patients is without diagnostic significance. A safe method for dealing with polyps of the stomach, therefore, appears to be surgical removal of the lesions.

SAMUEL KAHN, M D

End Results in the Treatment of Cancer of the Stomach

GEORGE T. PACK and GORDON MCNEER
Surgery, 1948, 24: 769

Gastric cancer is the most common and one of the most rapidly fatal of all cancers. Nevertheless, the hope for cure is a very definite one and is becoming greater as the years go by. The 5 year cure rate for 795 patients treated from 1912 through 1941 was 3.4 per cent. Of 75 patients surviving gastrectomy, 26, or 34.7 per cent, lived 5 years without recurrence.

If more gastric cancers are to be recognized in their early curable stage, strict attention must be paid to the earliest symptoms which are:

- 1 Simple indigestion in any person of middle or late life
- 2 The ulcer syndrome appearing for the first time in a person past 40 years of age. Until proved otherwise, this patient should be considered as having cancer of the stomach.
- 3 Secondary anemia without known cause
- 4 An awareness that all is just not right, or "stomach consciousness." Probably this is the earliest symptom of gastric cancer.

When any of these symptoms occur, GI series and fluoroscopy by a competent radiologist must be done. Only by these means will more gastric cancer be recognized in the early curable stage.

An analysis of 795 patients suffering from gastric cancer and treated in the Memorial Hospital for Cancer and Allied Diseases, New York, from 1916 through 1941, shows a steady increase in operability and resectability, and a steady decrease in operative mortality despite the fact that formerly palliative operations were common while now curative resections are the trend.

The operability of cancer of the stomach has increased steadily through successive 5 year periods, from 51.8 per cent to the present 82.7 per cent, and the resectability (of all cases) from 2.9 per cent to 39.8 per cent, while the operative mortality has decreased from 62.5 per cent to 21.7 per cent. The decrease in mortality has occurred despite the fact that during the past 5 years 42.8 per cent of all gastric resections for cancer were of a major character, i.e., total gastrectomy or transthoracic cardiotomy. In 92 subtotal gastrectomies the operative mortality was but 9.8 per cent.

Other factors which influence the end results are:

Duration of symptoms. The average duration of preoperative symptoms in 66 patients operated on between 1931 and 1941 was 9.7 months. The dura-

Period	Total cases	Operable cases per cent	Resectable			Operative mortality per cent
			Number	Operable cases per cent	Total per cent	
1916-1930	272	51.8	8	5.7	2.9	62.5
1931-1936	245	60.8	19	12.8	7.7	31
1937-1941	278	73.7	76	35.6	26.2	19
1942-1946	405	82.7	161	48.1	39.8	21

tion of symptoms for those surviving less than 5 years and those surviving more than 5 years following operation was approximately the same, i.e., 9 months and 9.3 months, respectively.

The gross pathological type of cancer. The 5 year survival without recurrence following resection of the various gross types was 22.7 per cent for the annular, 25 per cent for the infiltrating, 26.3 per cent for the polypoid, 33.9 per cent for the ulcerative and 100 per cent for carcinoma *in situ*. Thus annular carcinomas are the most fatal type, and carcinoma *in situ* is the least fatal.

The presence of metastases in the regional lymph nodes. The influence of metastases to the regional lymph nodes on 5 year survival was shown by a 22 per cent 5 year survival when metastases were present and a 42.8 per cent 5 year survival when they were absent.

Stated differently, of the patients who survived 5 or more years, 69.2 per cent had no lymph node metastases, while among those who had metastases the 5 year survival rate was but 30.8 per cent.

Serosal penetration. Fifty per cent of 16 patients having this complication had a 5 year cure, even though in 6 metastatic cancer was present in the regional lymph nodes.

The microscopic grade. Five year cures were obtained among the various microscopic grades of malignancy as follows: grade 1, 100 per cent; grade 2, 41.7 per cent; grade 3, 30 per cent; and grade 4, 16.7 per cent. Thus, grade 1 cancer is highly curable and grade 4 is far from hopeless.

Gelatinous or mucinous types of cancer have poor prognosis, probably because the mucin together with the cancer cells permeates the subserosal lymphatics early, and results in diffuse peritoneal carcinosis. Only 2 (21%) of 9 patients with such a cancer lived 5 years after resection, although in 7 there were no metastases in the perigastric lymph nodes.

FRANK B. QUEEN, M.D.

Physiological Aspects of Vagotomy

J. E. THOM and S. A. KOMAROV *Gastroenterology*, 1948, 14: 473

The authors point out that the striking physiological aspects of vagotomy on experimental animals have aroused the curiosity of investigators for at least the past 300 years. However, the effects of complete severance of the vagus nerves on gastro-

testinal functions were not adequately observed until Pavlov devised a method for preventing the early death of the experimental animal, which regularly followed vagotomy done through a cervical incision. When the vagus nerves were cut in the neck the animals generally died of asphyxia or aspiration pneumonia, or they starved to death because of disturbances in the swallowing mechanism. By using dogs with a gastric fistula and cutting one of the vagus nerves below the level of the recurrent laryngeal nerve, Pavlov and others learned to circumvent many of the original difficulties.

In animals prepared by Pavlov's technique it was found that gastric digestion was inadequate to cope with the ordinary nutritional requirements of an animal on a normal diet. Food stagnated in the esophagus and stomach, and special precautions were necessary to prevent death of the animal. It was the rule in the Pavlov laboratory that only those animals which failed to secrete acid when sham-fed were considered to have had their gastric vagus fibers completely severed. In 1896 Pavlov, considering his studies and those reported in the literature of the time, concluded that the consequence of complete vagotomy which was most dangerous to life was the impairment of the digestive processes including disturbances of the gastrointestinal motility and the secretory function of the stomach, pancreas, and possibly the intestine. He also emphasized the extreme vulnerability of the intestine.

The authors point out that the exact relation of the vagus nerves to gastrointestinal function is one of the more obscure problems of physiology. At times the vagus nerves appear to initiate functions as do true motor or secretory nerves. At other times they appear merely to augment or inhibit response to local stimuli. Following vagotomy the loss of tonic activity appears to be of major importance in the deterioration of function that follows vagotomy. Although no specific function is lost, the muscle appears to be relaxed and flabby and does not react with normal vigor to such local stimuli as distention of the stomach wall. Doubtless, also, the gland cells are affected in a similar way, but because of the nature of their function the changes are less easily characterized. Not only is the cephalic phase of secretion absent because of loss of vagal innervation but responses to the local stimuli normally producing the gastric and intestinal phases may be feeble or altogether absent.

The authors stress the fact that complete vagotomy in experimental animals regularly causes nutritional disturbances severe enough to cause death of the animal. These changes are characterized by hypomotility of the stomach and hyposecretory function.

The authors review the evidence, both experimental and clinical, and they believe that transthoracic or transabdominal vagotomy is seldom complete and that apparent discrepancies in experimental results can be explained by the differences in the completeness of the vagotomy. They also suggest that

the relative harmlessness of this operation in man is due specifically to its incompleteness. Any attempts to accomplish a more nearly complete vagotomy in human subjects is thought to be unwise. The guaranteed severance of all vagal fibers may lead to quite unfavorable results.

EDWARD F. LEWISON, M.D.

Gastrointestinal Motility Following Vagotomy and the Use of Urecholine for the Control of Certain Undesirable Phenomena THOMAS E. MACHELLA and STANLEY H. LORBER *Gastroenterology*, 1948, 11, 426

Changes in gastrointestinal motility may be due to alterations in either the extrinsic or intrinsic innervation. The extrinsic innervation consists of the sympathetic and the parasympathetic systems. The intrinsic innervation consists of at least two plexuses, Auerbach's and Meissner's. The vagus nerves supply parasympathetic innervation to the alimentary tract down to and including the proximal half or third of the transverse colon.

The authors briefly review the experimental and clinical evidence for the alterations in gastrointestinal physiology associated with vagus section, and report (1) cardiospasm, (2) gastric dilatation, hypotonus, and delayed emptying time, and (3) changes in intestinal motility.

This study is based upon 24 patients who have been subjected to vagotomy and upon 2 others who had their vagi interrupted together with resection of the fundus of the stomach and the lower esophagus for a high ulcer. Ten of these patients had no ancillary operative procedure other than vagotomy, while 16 had some form of anastomosis prior to, or simultaneous with, vagotomy.

In studying the effects of vagotomy upon gastrointestinal motility the most common motor disturbance observed by these investigators was gastric retention, and absent or diminished antral peristalsis. The time required for barium to move from the duodenum to the cecum was delayed probably as a result of poor emptying of the stomach.

In one patient, dynamic ileus was noted, and in another, dilatation of the entire small intestine. Motility disturbances secondary to an obstructing duodenal ulcer, to obstruction at or near the site of a gastroenterostomy stoma, or to obstruction of the esophagus at the operative site was observed. Such mechanical obstructive factors are to be kept in mind when symptoms of retention or obstruction are observed following vagotomy. No significant changes in the motility of the colon were noted by the authors. Spontaneous gastric emptying, sufficient to afford relief from symptoms of retention, occurred in all patients in whom the retention was secondary to vagotomy alone, after intervals varying from 2 to 12 months.

The authors discuss their experience in using urecholine for the treatment of postvagotomy complications and emphasize the little known fact that absorption from the small intestine must occur if

oral administration is to be effective Their routine in using the drug is outlined

EDWARD F LEWISON, M D

New Observations on the Oral Opaque Enema of the Small Intestine (Nuove osservazioni sul clisma opaco transbuccale del tenue) ANTONIO LURÀ. *Arch ital mal app diger*, 1948, 14 386

The term "oral opaque enema of the small intestine" is applied by the author to the introduction of an opaque medium through a duodenal tube for the purpose of visualization of the small intestine

The method allows visualization of the entire small intestine and sometimes also a portion of the large intestine The advance of the opaque column can be studied

The method is valuable for the detection of a neoplasm of the small intestine It is superior to oral administration of an opaque medium because the customary method may yield unsatisfactory results in the presence of a pylorospasm or a partial pyloric obstruction Also, in the presence of vomiting, direct introduction of a barium suspension into the duodenum is obviously preferable to ingestion of the opaque medium A vicious circle following gastroenterostomy can be visualized

JOSEPH K NARAT, M D

A Contribution to the Study of the Arterial Circulation at the Angle of the Duodenum, Jejunum, and the First Intestinal Loop (Contributo allo studio della circolazione arteriosa dell'angolo duodenale e della prima ansa intestinale) G OMEGNA and S NEGRETTO *Chirurgia*, 1948, 3 280

The authors studied the arterial circulation in the region of the ligament of Treitz by injecting the superior mesenteric artery at its origin in 20 cadavers They describe a branch known as the artery of the duodenojejunal angle which arises from the inferior pancreaticoduodenal artery or from one of its branches Rarely, it arises from the first intestinal artery This artery which is small in caliber often constitutes the only blood supply to the first loop of the jejunum Even when there is an anastomosis with the first intestinal branch the superior portion has fewer collateral vessels than the inferior portion This causes a deficiency of secondary arches to the superior portion of the first jejunal loop

The authors wish to stress the value of this finding when gastric surgery is to be done, especially when a gastroenterostomy for marginal ulcer is broken down, and end to end anastomosis of the first part of the jejunum is necessary As one proceeds distally the blood supply becomes better and better For this reason they recommend that in performing an ordinary gastroenterostomy the jejunal loop should be at least from 7 to 10 cm in length

The authors also describe the terminal branches of the vasa recta and the marginal arch of Drummond They emphasize that the intestine should be opened along its free margin or antemesenteric border in order to conserve the blood supply equally on both

sides when a gastrojejunal anastomosis is accomplished This also makes for better hemostasis When it is necessary to divide the intestine this should be done at right angles to the long axis of the bowel because the terminal branches follow a perpendicular course and do not anastomose very freely The section may be oblique, with the mesenteric side longer than the antemesenteric side, but never shorter

LUCIAN J FRONZUTI, M D

Intussusception in Childhood ROBERT E GROSS and PAUL F WARE *N England J M*, 1948, 239 645

This report covers the diagnosis, treatment, and results of therapy in 610 cases of intussusception, including 372 cases reported by Ladd and Gross in 1934

Emphasis is placed upon early diagnosis The authors' statistics show an increase in earlier diagnoses and a lowered mortality for the late cases in the period from 1934 to 1947 as compared to the earlier series

The etiology remains obscure, mechanical factors (diverticuli, polyps) having been found in only 5.4 per cent of the entire series

Diagnosis is relatively simple in 9 of 10 cases and can be made on the basis of the sudden onset of paroxysmal pain, vomiting, gross or occult blood in the stool (10 or 12 hours after onset of the pain), and a palpable abdominal mass Rectal examination with bimanual palpation of the abdomen will increase the number of cases in which an intra-abdominal mass can be felt When doubt remains a barium enema will confirm the diagnosis in most instances since in from 90 to 95 per cent the colon is involved as the receiving segment of the intestinal tract

In general, the authors do not feel that reduction by hydrostatic pressure should be attempted because of the delay caused by the procedure, and the possibility of missing a specific mechanical cause or leaving a small bowel or ileoileocolic intussusception incompletely reduced

Rapid preparation of the child for surgery is accomplished with glucose, plasma, or blood, as indicated, and a right rectus muscle incision is used The intussusception is reduced by taxis rather than by traction and the viability of the intestine is determined by improvement of color or the occurrence of peristalsis in the involved segment

If the intussusception is irreducible, or the viability of the bowel in doubt, resection must be done In addition, when dealing with a very ill patient, resection should be done without any attempt at reduction since the authors believe reduction has a deleterious effect on the patient which may be fatal under these circumstances

The authors favor the aseptic, Mikulicz resection because of the low mortality (23 per cent) in their series as compared with the mortality when primary anastomoses (83 per cent) or open enterostomies (77 per cent) were done

Postoperatively, gastric suction and fluid therapy are used and fluids are given as tolerated after 24 hours. If resection has been done, the patient must be very carefully followed up for a longer time and parenteral fluids used to control plasma levels of chloride, protein, and carbon dioxide combining power. From 1946 to 1947 the over-all mortality was 2.7 per cent. With the Mikulicz resection they have had only 1 death in 11 resections in the last 9 years.

JOHN H. KAY, M.D.

Anastomosis of the Ileum to the Lower Part of the Rectum and Anus. A Report on Experiences with Ileorectostomy and Ileoproctostomy, with Special Reference to Polyposis. R. RUSSELL. *BEST Arch Surg*, 1948, 57: 276.

This article is a report of the author's experiences with anastomosis of the terminal ileum to the lower 4 inches of the rectum and directly to the anus. In this series the operation was done in 5 cases of polyposis with associated malignant degeneration of the rectum and in an additional 4 cases of advanced carcinoma of the rectum without polyposis.

The chief indications for anastomosing the terminal aspect of the ileum to the lower part of the rectum or anus are polyposis of the colon and the rectum when carcinoma has developed in the rectum, and the patient's desire to avoid an ileostomy. At the present time the author does not believe the ileorectostomy or ileoproctostomy should be attempted in routine cases of rectal carcinoma in order to preserve the sphincter mechanism or when it is impossible to bring the sigmoid and rectum into apposition. From the complications which appeared in these cases it would appear that a colostomy should be chosen in preference to attempting to preserve the sphincter mechanism by side-tracking the colon and hooking the terminal ileum to the lower part of the rectum or anus until further refinements of techniques have been developed.

It appears that the best operation in the present series is a telescoping procedure whereby a rectal tube is forced into the ileum and the tube is drawn out through the anus. Interrupted sutures complete the anastomosis. This can be accomplished entirely from within the abdomen or by a combined method of abdominal dissection and posterior anastomosis. Because of the incidence of rather excessive posterior drainage or development of fistula, establishment of posterior drainage of the presacral space is indicated.

Considerable effort must be directed toward decreasing the frequency of bowel movements during the postoperative period. This includes the energetic use of paregoric and milk of bismuth and tannic acid products. A low residue constipating diet is of assistance. After several weeks bowel movement frequency usually stabilizes itself at about 3 to 6 stools during the 24 hours unless a complicating stubborn posterior fistula or stricture develops. This complication results in almost constant posterior drainage.

Hypoproteinemia is rather pronounced during the early weeks postoperatively, but a normal level usu-

ally establishes itself after some 3 to 4 weeks, provided efforts toward a high protein intake are made. When the distal part of the ileum is anastomosed to the terminal part of the rectum or anus it becomes dilated, the wall hypertrophies, and the absorptive function and storage capacity apparently increase.

HAROLD LAUFMAN, M.D.

Anemia Following Resection of the Intestine. J. D. MARTIN, JR., ROY L. ROBERTSON, and EDWARD W. DENNIS. *Surgery*, 1948, 24: 819.

Anemia following intestinal resection may be of three types. A normochromic normocytic anemia may occur immediately after operation and is due to blood loss. A secondary hypochromic anemia may occur as a result of nutritional disturbances. A macrocytic hyperchromic anemia may occur as a result of the deficient production or absorption of the erythrocyte maturing factor.

Two cases in which anemia developed following extensive resection of the intestine are discussed. The condition of both patients improved dramatically on folic acid therapy. From a review of the literature it appeared that in both of these patients the anemia was due to faulty or absent absorption or production of substances that ordinarily combat macrocytosis and hyperchromia, namely, the anti-pernicious anemia factor and vitamin B.

In an attempt to produce a hyperchromic macrocytic anemia in adult dogs, massive resections of the small intestine were performed. Of 12 animals used, only 4 survived a sufficient length of time for study. In these a characteristic sequence of events was observed. At first hemoconcentration occurred because of dehydration from diarrhea and low fluid intake. After adequate fluid intake was resumed approximately normal counts were obtained. However, from 3 to 4 weeks after operation the red cell count and hemoglobin began to drop progressively to low levels. Reticulocytes were extremely rare or absent. Changes in volume and color index were not constant, and no definite trend toward macrocytosis could be established. No response was noted to folic acid therapy, in contrast to the response seen in human beings, and this suggests that the more severe anemia produced in the animal is not entirely due to the same causes as that seen in the clinical cases.

EDWARD W. GIBBS, M.D.

Evaluation of Conservative Resection with End-to-End Anastomosis for Carcinoma of the Rectum and Lower Sigmoid Colon. JESSIE GRAY. *Arch Surg*, 1948, 57: 361.

The author's opening paragraph states succinctly the purpose of her report. "This paper is not a crusade for resection of the rectum with restoration of continuity. It is an honest endeavor to assess the place of conservative resection, if any, in the operative therapy of rectal carcinoma. Certain facts are presented, and certain conclusions are drawn. Facts cannot be questioned, but conclusions should be critically assessed."

Seventy-four cases of conservative resection with end-to-end anastomosis for carcinoma of the rectum and rectosigmoid region are reviewed. The operative mortality among these patients was 4 per cent. The expected relationship of survival to stage of the disease was confirmed. Eighty per cent of patients in the group with stage I carcinoma were alive and well, 52 to 59 per cent of those in the groups with stages II and III carcinomas have survived, and only 25 per cent of patients in the group with stage IV carcinomas were alive and well at the time of writing.

The expected relationship of survival to gland involvement was confirmed. Fifty-seven per cent of patients without secondary involvement in glands were alive and well, while only 39 per cent of those with gland involvement have survived.

Results of conservative resection are found to be related to the anatomic level of the tumor in the bowel. Only 17 per cent of the patients whose growths arose below the bottom of the pouch of Douglas have survived. The percentage survival of patients with carcinomas at other levels is found to depend on the stage of the disease and on gland involvement of the tumor. The highest percentage of good results is obtained in growths of upper rectal level. This is attributed to the relative avascularity of this portion of the bowel with resultant slower growth and spread of carcinomas arising at this level.

Unless a carcinoma is definitely polypoid in type and freely movable, resection with preservation of the anal canal should not be undertaken when the growth is readily within reach of the examining finger per rectum.

The development of local recurrence of disease is found to have no special relationship to the stage of disease or gland involvement, but a distinct relationship to anatomic level of the tumor in the bowel. Forty-three per cent of the local recurrences have occurred among the patients with carcinomas below the peritoneum, which comprise only 16 per cent of the entire series.

If conservative resection had been reserved for patients whose carcinomas were above the peritoneum, only 3 per cent would have had recurrences which might conceivably have been avoided by total extirpation of the rectum.

Eighty per cent of patients operated on within the 5 years prior to writing were alive and well as compared with only 42 per cent of those with resection done more than 5 years previously. Evidence is brought forth to support the belief that this is due, in a large part, to improved management in recent years. A higher percentage of 5 year cures is to be expected in the future, particularly if conservative resection is reserved for tumors above the peritoneum.

All of the deaths in the entire series were analyzed as to cause, survival time, and debatability in reference to the type of operation performed. Among 62 patients with growths above the peritoneum, conservative resection resulted in only 2 deaths which,

because of the level stage and gland involvement of the carcinomas, might conceivably have been prevented by abdominoperineal resection.

Analyses of results in this series indicate that since the results above the bottom of the pouch of Douglas are only 3 per cent less favorable than those which might be obtained by total extirpation of the rectum, the obviation of a permanent colostomy warrants this 3 per cent increase of risk of failure to cure the patient when the carcinoma occurs above the peritoneum.

HAROLD LAUFMAN, M D

The Surgery of Complications of Ulcerative Colitis

L. KRAEER FERGUSON and LLOYD W. STEVENS
Gastroenterology, 1948, 11: 640

Delay in surgical intervention in ulcerative colitis is frequently justified on the basis of a forbidding mortality, and the belief that ileostomy dooms the individual to a life of restricted activity. These are misconceptions. The surgical mortality of ileostomy is currently less than 5 per cent, and the mortality for colectomy is even less. The handicap of an ileostomy has also been eliminated to a great extent. With the Koenig-Rutzen type of ileostomy bag, the average patient is able to assume fairly normal economic and social activity. Procrastination may cause death from ulcerative colitis.

Perforation, uncontrolled hemorrhage, and obstruction occur after diversion of the fecal stream as well as in the actively functioning colon. Ileostomy offers no insurance against their appearance. It has been said that these patients are too sick to be operated on. In reality, they are too sick not to be operated on. Emergency colectomy is feasible in the treatment of certain cases of perforation and uncontrolled hemorrhage.

Colectomy is indicated also in the presence of long standing irreversible mucosal changes, polyposis, granulomatous masses, and obstructive lesions. In the presence of these lesions, it should not be delayed for long periods of time.

Any colon which has been defunctionalized as a result of ileostomy should be observed periodically. If no indication for colectomy is found, barium enemas and sigmoidoscopic studies should be made from time to time, to discover early evidence of complications. Only in this way can the threat of rapidly metastasizing tumor be removed.

SAMUEL KAHN, M D

Rectal Stricture of Lymphogranuloma Venereum

LESTER BREIDENBACH and LOUIS R. SLATTERY
Ann Surg, 1948, 128: 1079

Reports of the experiences of many other surgeons are discussed in the present article, and 18 new cases of rectal stricture of lymphogranuloma venereum are presented in outline form. The ages of the patients varied from 20 to 40 years, with colored females predominating. The typical patient is a poorly nourished, exhausted, colored female. The abdomen shows varying degrees of distention, crampy pains and intractable diarrhea are usually

present, secondary anemia is often associated with slight leucocytosis, plasma proteins are low and the albumin-globulin ratio may be reversed, the Frei test is always positive

The first step in the treatment of patients is to restore them to their normal physiologic condition. To accomplish this, a completely defunctioning colostomy is performed, usually in from 5 to 7 days after admission. The second step is removal of the local focus, which is performed 1 to 6 months later. The operative procedure is described. An inverted "Y" incision is made over the end of the sacrum and around the anus, the lower portion is turned down. The local focus is completely excised, the proximal sigmoid or colon is brought down to the distal segment, and an anastomosis is performed. In the authors' cases, the result of this procedure seemed satisfactory. The third stage of the operation is closure of the colostomy, which is performed, usually, in 4 to 6 weeks following the resection, when the anastomosis and posterior wall are well healed.

All patients who submitted to the completed operation have been restored to normal health. There were no fatalities among the 18 patients subjected to resection. Sphincter control has been attained in all cases.

RICHARD J. BENNETT, JR., M.D.

Streptomycin and Surgery in Anorectal Tuberculosis E. RANSOM KOONTZ *Surg Clin N America*, 1948, 28: 1643

A series of 27 cases of anorectal tuberculosis is reported. The patients were treated with streptomycin with and without definitive surgery. Streptomycin therapy supplemental to surgical incision or excision was carried out in 19 cases, and healing occurred in 100 per cent of the cases. In these cases streptomycin was used as an adjunct to recognized proctologic surgical procedures, and meticulous post-operative treatment was not neglected. There were 8 patients who received streptomycin alone. Of this group, healing was obtained in 4 patients while some improvement occurred in the others.

In selected cases in which surgery is contraindicated or deemed inadvisable, streptomycin therapy alone may be utilized with some promise of success but the results will not be as gratifying as when surgery and streptomycin are combined. Streptomycin therapy makes possible in certain cases the performance of a less extensive surgical procedure than formerly would have been justified. It also enables the surgeon to institute surgical treatment of anorectal tuberculosis at an earlier stage in the hospitalization and treatment of the patient with pulmonary tuberculosis and serves as a protection against spread and exacerbation of the pulmonary disease during surgical treatment.

The author believes that streptomycin therapy supplemental to surgery definitely shortens the post-operative period required for healing and prevents recurrence. There was no recurrence in his patients which he treated in this manner.

JOHN L. LINDQUIST, M.D.

Carcinoma of the Anal Canal J. L. ROUV-BERGER and A. ENNUYER *Am J Roentg*, 1948, 60: 807

The authors present an argument in favor of radiotherapy for carcinoma of the anal canal. All lesions in this series were of epithelial origin and therefore considerably more radiosensitive than adenocarcinoma of the rectum. There were 18 five year cures in a series of 51 cases, or a 35 per cent 5 year curability rate.

The authors consider radiation to be the only treatment which gives a chance of avoiding permanent colostomy. However, a comparison of radiotherapeutic and surgical results is impossible for want of a sufficient number of 5 year statistics. The number of failures following radiotherapy is still large, but the authors believe that if the treatment were carried out earlier, when the lesions were still small, the number of cures would be greatly increased. In 11 patients in whom the primary lesion did not extend beyond the limits of the anal canal, 7 were cured.

The authors have abandoned radium implantation in favor of contact roentgen therapy for small lesions and supervoltage roentgen therapy for larger lesions extending outside the anal canal. An evaluation of the correctness of this change cannot be made at this time.

It is the authors' contention that the hope of preserving a normal anus, the results which they have obtained, and the technical improvements which are at present in operation, justify the use of radiation as the primary treatment for carcinoma of the anus. If this method of treatment fails, surgical removal can be carried out, provided the previous radiotherapy has not made operation impossible.

HAROLD LAUFMAN, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

The Nervous Hypergenesis of Cholecystitis (L'hy- pergénése nerveuse des cholécystites) L. CORNIL, H. GASTAUT, J. CHARPIN, and H. PAYAN *Presse méd*, 1948, No. 57: 669

These authors call attention to the frequent occurrence of areas of hyperplasia of the nervous tissue in the adventitia of the gall bladder wall found on microscopic section of surgically removed gall bladders. These areas are comparable in histologic structure to the so-called amputation neuromas. They seem in no way related to the neurofibromatosis of Recklinghausen and would appear to be in some way a result of preceding severe inflammatory changes in the gall bladder wall.

EDWARD W. GIBBS, M.D.

Postcholecystectomy Symptoms Due to Cystic Duct Remnant CHARLES BRUCE MORTON, II *Surgery*, 1948, 24: 779

Symptoms referable to the biliary tract following cholecystectomy may have a varied etiology. Stones in the ducts, strictures or angulations of the duct, cholangitis, hepatitis, and pancreatitis are some of the etiologic agents.

The author wishes to emphasize that the remnant of the cystic duct left at the time of cholecystectomy may be the cause for persisting or recurring symptoms. He reports 7 personal cases in which operation revealed a cystic duct remnant to be apparently the sole cause of postcholecystectomy symptoms. He therefore concludes that meticulous care should be exercised at the time of cholecystectomy to remove the entire cystic duct. F J LESEMAN, JR., M D

Late Results of Cholecystectomy The Factors Involved in Failures and in Recurrences Personal Experience of the Clinic at Naples (I risultati lontani della colecistectomia fattori di insuccesso e di recidiva. La esperienza della nostra clinica) LUIGI IMPERATI *Gior ital chir*, 1948, 4 547

This is the second communication concerned with the analysis of the causes of failure in surgery of the gall bladder. The first appeared in the previous issue (August number) of this journal. The material reported in this second communication consists of 118 patients who underwent the original operation and 36 who had previously been operated upon in the author's clinic or elsewhere. The follow-up technique consisted of personal visits of the patient or of answers to a questionnaire. This study could be carried out only in 36 instances because of the exigencies of war, however, the patients reporting presented various types of lesions and the follow-up was conducted at varying periods of time following the clinic treatment, and therefore the findings are regarded as closely illustrative.

In the group of original operations a careful distinction is made between the lithiasic cases and the a-lithiasic gall bladder. In the former the results were regarded as satisfactory in 88.5 per cent of the cases, as mediocre in 8.5 per cent, and as negative in 3 per cent. In the a-lithiasic group the results were regarded as satisfactory in 21.4 per cent, as mediocre in 48.8 per cent and as negative in 29.8 per cent. Of course, the percentage of failures in this material is rather high, but it is ascribed to the greater willingness of those who still suffer, or again suffer, pain and disability to reply to the rather long and involved questionnaire.

As regards the results obtained in the 36 patients who were relaparotomized for continued or recurrent suffering following the original cholecystectomy, such information as is available indicates that the results were satisfactory in 6 cases of repair of a laparocoele, in 3 cases of intestinal occlusive symptoms in which excision of the adhesions was done, in 2 cases of ulcer duodenale following excision and gastroenterostomy, and in 2 cases of gynecological conditions (1 case of cystic ovary and 1 of fibroids of the uterus). The results were satisfactory in about 50 per cent of the 3 cases of chronic adhesions and 10 cases of the acute and chronic appendicitis syndrome.

As regards the treatment, the experiences here encountered led to the conclusion that the treatment of calculous cholecystitis is strictly surgical,

and the earlier surgery is instituted, the better. Although the author does not maintain that the treatment for the noncalculous, or a-lithiasic, syndromes is never surgical, yet in the clinic at Naples operation in these cases is becoming ever more rare. He believes that every resource of physical and laboratory examinations, and of all conservative therapy should be exhausted before these patients, as well as patients with postcholecystectomy syndromes, are sent to the operating room.

Special emphasis is placed by the author on the diagnostic advantages to be gained by cholangiography carried out during the laparotomy itself and the therapeutic help to be expected in the nonoperative cases from duodenal drainage.

JOHN W BRENNAN, M D

The Silent Gallstone a 10 to 20 Year Follow-Up Study of 112 Cases MANDRED W COMFORT, HOWARD K. GRAY, and JAMES M WILSON *Ann Surg*, 1948, 128 931

The problem of the silent gallstone has become an increasingly frequent and an increasingly important one. Several pertinent questions are being asked concerning the frequency of occurrence and the advice which should be given the patient who has silent gallstones. Questions also arise concerning whether the patient should be told to undergo cholecystectomy or to await the development of dyspepsia or colic before submitting to surgical treatment, and whether he should be urged to undergo cholecystectomy after the first attack of colic or after several attacks have occurred.

The frequency with which the silent gallstone occurs in the general population is not known.

In the hope of supplying some of the data necessary for decision regarding treatment of the silent gallstone, a long-term follow-up study of all cases in which gallstones were found incidentally during the course of some other abdominal operation at the Mayo Clinic was carried out. The records of 998 such cases occurring from 1925 through 1934 were reviewed and 112 cases were considered suitable for study. The average age of the 112 patients was 48.2 years when the gallstones were discovered.

Although the data compiled do not give conclusive information about the risk of nonoperative and operative treatment of the silent gallstone, they are noteworthy on this basis: the patient with silent gallstone may be told that he has about an even chance that symptoms will develop, that he has about one chance in five that painful seizures will develop and a small chance that jaundice will develop within 10 to 20 years. In addition, he should be told that the risk of surgical intervention at the best is about 0.5 per cent when cholecystectomy is performed before complications develop, that the risk will increase to about 3 per cent if he defers surgical intervention until complications develop, or old age and physical debilities appear, but that the increase in risk is counterbalanced by the fact that if he defers surgical intervention he may never re-

present, secondary anemia is often associated with slight leucocytosis, plasma proteins are low and the albumin-globulin ratio may be reversed, the Frei test is always positive

The first step in the treatment of patients is to restore them to their normal physiologic condition. To accomplish this, a completely defunctioning colostomy is performed, usually in from 5 to 7 days after admission. The second step is removal of the local focus, which is performed 1 to 6 months later. The operative procedure is described. An inverted "Y" incision is made over the end of the sacrum and around the anus, the lower portion is turned down. The local focus is completely excised, the proximal sigmoid or colon is brought down to the distal segment, and an anastomosis is performed. In the authors' cases, the result of this procedure seemed satisfactory. The third stage of the operation is closure of the colostomy, which is performed, usually, in 4 to 6 weeks following the resection, when the anastomosis and posterior wall are well healed.

All patients who submitted to the completed operation have been restored to normal health. There were no fatalities among the 18 patients subjected to resection. Sphincter control has been attained in all cases.

The material reported in this second communication consists of 118 patients who underwent the original operation and 36 who had previously been operated upon in the author's clinic or elsewhere. The follow-up technique consisted of personal visits of the patient or of answers to a questionnaire. This study could be carried out only in 36 instances because of the exigencies of war, however, the patients reporting presented various types of lesions and the follow-up was conducted at varying periods of time following the clinic treatment, and therefore the findings are regarded as closely illustrative.

In the group of original operations a careful distinction is made between the lithiasic cases and the a-lithiasic gall bladder. In the former the results were regarded as satisfactory in 88.5 per cent of the cases, as mediocre in 8.5 per cent, and as negative in 3 per cent. In the a-lithiasic group the results were regarded as satisfactory in 21.4 per cent, as mediocre in 48.8 per cent and as negative in 29.8 per cent. Of course, the percentage of failures in this material is rather high, but it is ascribed to the greater willingness of those who still suffer, or again suffer, pain and disability to reply to the rather long and involved questionnaire.

As regards the results obtained in the 36 patients who were relaparotomized for continued or recurrent suffering following the original cholecystectomy, such information as is available indicates that the results were satisfactory in 6 cases of repair of a laparocoele, in 3 cases of intestinal occlusive symptoms in which excision of the adhesions was done, in 2 cases of ulcer duodenale following excision and gastroenterostomy, and in 2 cases of gynecological conditions (1 case of cystic ovary and 1 of fibroids of the uterus). The results were satisfactory in about 50 per cent of the 3 cases of chronic adhesions and 10 cases of the acute and chronic appendicitis syndrome.

As regards the treatment, the experiences here encountered lead to the conclusion that the treatment of calculous cholecystitis is strictly surgical,

and the earlier surgery is instituted, the better. Although the author does not maintain that the treatment for the noncalculous, or a-lithiasic, syndromes is never surgical, yet in the clinic at Naples operation in these cases is becoming ever more rare. He believes that every resource of physical and laboratory examinations, and of all conservative therapy should be exhausted before these patients, as well as patients with postcholecystectomy syndromes, are sent to the operating room.

Special emphasis is placed by the author on the diagnostic advantages to be gained by cholangiography carried out during the laparotomy itself and the therapeutic help to be expected in the nonoperative cases from duodenal drainage.

JOHN W BRENNAN, M D

The Silent Gallstone a 10 to 20 Year Follow-Up Study of 112 Cases MANDRED W COMFORT, HOWARD K GRAY, and JAMES M WILSON *Ann Surg*, 1948, 128, 931

The problem of the silent gallstone has become an increasingly frequent and an increasingly important one. Several pertinent questions are being asked concerning the frequency of occurrence and the advice which should be given the patient who has silent gallstones. Questions also arise concerning whether the patient should be told to undergo cholecystectomy or to await the development of dyspepsia or colic before submitting to surgical treatment, and whether he should be urged to undergo cholecystectomy after the first attack of colic or after several attacks have occurred.

The frequency with which the silent gallstone occurs in the general population is not known.

In the hope of supplying some of the data necessary for decision regarding treatment of the silent gallstone, a long-term follow-up study of all cases in which gallstones were found incidentally during the course of some other abdominal operation at the Mayo Clinic was carried out. The records of 998 such cases occurring from 1925 through 1934 were reviewed and 112 cases were considered suitable for study. The average age of the 112 patients was 48.2 years when the gallstones were discovered.

Although the data compiled do not give conclusive information about the risk of nonoperative and operative treatment of the silent gallstone, they are noteworthy on this basis: the patient with silent gallstone may be told that he has about an even chance that symptoms will develop, that he has about one chance in five that painful seizures will develop and a small chance that jaundice will develop within 10 to 20 years. In addition, he should be told that the risk of surgical intervention at the best is about 0.5 per cent when cholecystectomy is performed before complications develop, that the risk will increase to about 3 per cent if he defers surgical intervention until complications develop, or old age and physical debilities appear, but that the increase in risk is counterbalanced by the fact that if he defers surgical intervention he may never re-

quire operation. It is not possible on the basis of information now available to tell the patient whether the risk is greater or smaller if operation is performed while the gallstones are silent than if it is postponed until symptoms develop. Certainly, the mortality rate will be low regardless of the choice made.

Cholecystectomy may be advised but need not be urged if the patient prefers to accept the chance of experiencing painful seizures or the increased risk of surgical treatment in the event the complication of calculous disease of the biliary tract appears.

Reflux into Wirsung's Canal in Course of Cholangiography *Dystonia of Wirsung's Canal* (Le reflux dans le canal de Wirsung au cours des cholangiographies) *Dystonies du canal de Wirsung*. P. MALLET-GUY, E. GUILLET, and L. DURAND. *Lyon chir.*, 1948, 43, 653.

Cholangiographic studies were done by the authors on 800 patients. Of the 2,826 films, 1,329 were taken preoperatively and 947 after the operation. In 173 cases, or 21.6 per cent of the entire material, a reflux of the opaque material into the main pancreatic duct was noticed. In 65 cases the opaque medium was introduced into the gall bladder, in 100 cases directly into the common duct, and in 8 cases into both.

An analysis of the technical factors and the clinical observations showed that no reflux occurred in patients with intact biliary and pancreatic systems. A reflux of the opaque medium into Wirsung's duct was recorded in 12 patients with mechanical obstruction of Vater's papilla, in 53 with a hypertonic sphincter of Oddi, in 36 with a hypotonic sphincter of Oddi, in 40 with chronic pancreatitis without disturbance of sphincter function, in 2 with acute pancreatitis, and in 30 with various pathologic conditions of the biliary system, among them 19 with attacks of jaundice.

The authors mention several sources of diagnostic errors. A reflux may be simulated by images of osseous structures or of the duodenum, or by duplication of the shadow of the common duct caused by respiratory movements. Conversely, difficulties in visualizing a reflux may be caused by a filiform duct of Wirsung or by the location of this duct behind the common duct.

The type of dystonia of Oddi's sphincter can be determined by manometric measurements.

The phenomenon of the reflux disappears after elimination of the dystonia, namely, splanchnicectomy for hypotonus, and infiltration of the vagus nerve, sphincterotomy, or medical treatment (administration of beta-phenylisopropylamine sulphate or inhalation of amyl nitrite) for hypertonus.

The authors introduce a concept of dystonia of the main pancreatic duct which in turn may produce pancreatic lesions. They advance the hypothesis of a painful functional syndrome of the pancreas, comparable with a similar condition of the biliary tract. Such a syndrome may be responsible for the symptomatology of the dystonia of the sphincter of Oddi. The existence of a reflux into Wirsung's duct in the presence of acute or chronic pancreatitis without

demonstrable lesions or functional disturbances of the sphincter of Oddi constitutes a physiopathologic problem that awaits elucidation.

JOSEPH K. NARAT, M.D.

Traumatic Rupture of the Choledochus Associated with an Acute Hemorrhagic Pancreatitis and a Bile Peritonitis N. FREDERICK HICKEN and VERNON L. STEVENSON. *Ann Surg.*, 1948, 128, 1178.

The authors present the case history of a 7 year old white boy who was injured by compression of the upper abdomen. The boy was treated immediately and dismissed. Four days later he was readmitted to the hospital because of nausea, vomiting, dehydration, and increased jaundice. His temperature was 104.8 degrees F. Emergency treatment was given, and after 4 days of intensive preoperative preparation, the abdomen was opened. At this time 2,300 c.c. of normal appearing bile were aspirated from the abdominal cavity, and 2,100 c.c. of bile were aspirated from the lesser omental cavity. In order to localize the tear in the common bile duct, 50 c.c. of a 70 per cent diodrast were injected into the collapsed gall bladder, and a cholangiogram was taken. The bile system was visualized, and it was considered that the edematous pancreas had occluded the opening into the duodenum, since none of the medium passed through the ampulla of Vater. A tear was visualized on the posteromedial wall of the common bile duct. A traumatic pancreatitis was the complicating factor. A cholecystostomy was used to decompress the common duct while the obstructive pancreatitis was subsiding.

Supportive therapy was administered. Subsequent cholangiograms showed that the tear in the common duct had healed and, finally, that once again the bile was flowing normally into the duodenum. The drain was then removed. A period of 10 months has elapsed since the injury, and the results have been satisfactory. A total of 8,900 c.c. of bile was aspirated from the abdominal cavity.

RICHARD J. BENNETT, JR., M.D.

Choledochus Cyst Associated with Congenital Atresia of the Bile Ducts CHARLES B. RIPSTEIN and G. GAVIN MILLER. *Ann Surg.*, 1948, 128, 1173.

The case of a female infant, age 4 months, is presented. The child had been jaundiced from the time of birth. At operation, a cyst of the common duct was found. This was associated with a congenital atresia of the bile ducts. The condition in this patient may have been due to abnormality in the development of the bile ducts.

RICHARD J. BENNETT, JR., M.D.

Postoperative Biliary Dyskinesia Due to Neuroma of the Cystic Duct (Disquinesia biliar post operatoria por neuroma del cístico) JUAN LEVY BOLA and DERES. *Bol. sec. san. pol. nac.*, 1948, 4, 470.

For several years a woman of 26 years had suffered from painful crises in the right hypochondrium and flank accompanied by frequent vomiting and a bitter

taste. She had been subjected to appendectomy and salpingectomy on the right side, but her symptoms persisted and she was finally seen by the author, who made the diagnosis of biliary dyskinesia due to atony of the gall bladder and recommended cholecystectomy.

At operation the gall bladder was removed and a separate ligation of the artery and cystic duct was performed, this was followed by choledochotomy and the introduction of a T-tube. The choledochus was of normal size and was surrounded by an abundant nerve plexus. Recovery was uneventful. The woman remained well for 14 months and then began to have slow digestion accompanied by nausea and occasional vomiting and 6 months later her symptoms were as bad as before the operation. The biliary dyssynergia was evidently of neurogenic origin. At operation the choledochus was exposed and a small tumor, about 1 cm in diameter, was found to be adhering to it at the site of implantation of the cystic duct, it was freed with a scissors and removed. Recovery was prompt and the patient has remained well. The specimen presented a small cavity corresponding to the obliterated canal, and its wall was thickened by proliferation of fibrosclerous tissue, section of the wall revealed massive enlargement of the neuromatous nerve endings.

For a number of years the author has performed direct cholecystectomy from the fundus to the cystic duct after placing a temporary hemostatic ligature on the pedicle. Now he incises the peritoneal fold which covers the cystic duct at its junction with the choledochus, dissects as far as possible the nerve filaments that pass from the choledochus to the cystic duct and resects them, he also dissects, if possible, the cystic artery, ligates and cuts it, and then proceeds as usual. If the inflammatory edema or the obesity of the patient does not allow correct performance of this step, he frees the gall bladder from the fundus to the cystic duct after placing the temporary hemostatic ligature, and then cleans the cystic duct of all tissue that surrounds it, and ligates the duct. When the temporary ligature is removed, it is easy to catch the cystic artery and to ligate it if it has not been previously tied off while the gall bladder was freed.

RICHARD KEMEL, M D

Recurrent Acute Pancreatitis. Observations on the Etiology and Surgical Treatment. HENRY DOUBILET and JOHN H. MULHOLLAND. *Ann Surg*, 1948, 128: 609.

The case histories of 21 patients exhibiting attacks of acute recurrent pancreatitis are recorded and analyzed with respect to the value of the surgical division of the sphincter of Oddi. The rationale of such treatment is twofold: it is dependent (1) upon an anatomic variation in the entrance of the main pancreatic duct into the duodenum which creates a common biliary-pancreatic passageway that permits bile to flow into the pancreas, and (2) upon the contention of Archibald that spasm of the sphincter of Oddi produces a bile diverting mechanism.

Studies on human patients with proved acute recurrent pancreatitis substantiate the contention that when a common passageway exists, spasm of the sphincter will produce the disease and sectioning of the sphincter will relieve it. It is well known that morphine, by producing spasm of the duodenal wall, increases the resistance of the sphincter to the flow of bile. Also the application of N/10 hydrochloric acid to the papilla of Vater will produce spasm of the sphincter of Oddi. After section of the sphincter muscle, the hydrochloric acid effect on the papilla is abolished. The sphincter can no longer become spastic and biliary reflux under pressure is prevented. However, the morphine effect on the duodenal wall persists. Thus, reflux of the duodenal contents into the biliary tract is prevented even though the sphincter has been sectioned.

The actual sectioning of the sphincter is a somewhat exacting procedure. The papilla is difficult to find and when the muscle is in spasm the orifice may be extremely small. The best approach is through the common bile duct. The duodenum may be opened over an instrument or over a probe. The muscle is then cut over the probe for about 1 cm in the anterior free or intraluminal portion of the duct. The retraction of the sphincter muscle fibers prevents healing or regeneration of the muscle.

ORVILLE F. GRIMES, M D

The Operative Diagnosis of Duodenal Pancreatic Indurations. (Diagnostico operatorio de las induraciones del duodeno-pancreas). LORENZO H. MARTARENA. *Bol Inst clin quir*, B. Air, 1948, 24: 91.

It is believed that because of the advancement in diagnosis and treatment of lesions of the head of the pancreas, a new anatomic entity, the duodeno-pancreas, should be taken into account. This is true particularly as this section has its own neurovascular individuality and its own pathologic anatomy.

Because obstructions from tumors are similar in their effect to obstructions from inflammatory processes, understanding of the duodenopancreas segment will prevent needless surgery, such as pancreatectomy, for a simple inflammatory condition. Diagnosis of this type of obstruction is facilitated by the routine palpation of the head of the pancreas. The surgeon will become familiar with the normal consistency of the structure, and as a result a silent lesion will not be overlooked.

When necessary, surgical exploration should be resorted to unhesitatingly. Exploration of the duodenopancreatic area for obstruction is easily accomplished by sectioning of the duodenal pancreatic ligament, diagnostic puncture of the obstruction, biopsy of the pancreas, biopsy of the ganglioperipancreatic area, biopsy of the hepatic metastasis, or exploratory duodenectomy.

Pancreatic obstruction may be classified into definite pancreatic or duodenopancreatic obstruction, or obstruction in the region of the ampulla of Vater.

It is stated that in patients with symptoms of biliary lithiasis without jaundice and in those pre-

senting cholelithiasis with a nodular obstruction in the head of the pancreas, the diagnosis of chronic pancreatitis secondary to lithiasis is justified

On the other hand, in patients with the same symptoms plus jaundice who present stones in the gall bladder or in the choledochal ducts with obstruction in the head of the pancreas, and who on choledochectomy reveal that the pancreatic obstruction is not of calculous origin and the obstruction is not from the choledochus, the condition is without a doubt secondary pancreatitis

However, in patients with painless jaundice, a tumor in the biliary or pancreatic ducts, despite normal appearance of these ducts (whether they be dilated or not), and an obstruction in the duodeno-pancreas area, the diagnosis of cancer is correct

STEPHEN A. ZIEMAN, M D

Pancreatolithiasis (La litiasi pancreatica) MARCELLO INNOCENTI *Ann ital chir*, 1948, 25 413

Among 20,000 surgical patients operated upon in Florence, stones in the pancreas were found only in 1, a man of 45 years. In addition to this case the author reports another in which the diagnosis was established clinically and roentgenologically. The patient, a 52 year old woman, was not operated on

The first patient was admitted with complaints of pain in the epigastrium and in the left upper quadrant of the abdomen of a few years' duration. The x-ray findings suggested the presence of a duodenal ulcer, in addition to it, a shadow with irregular outlines was visualized to the right and to the left of the vertebral column at the height of the stomach. The operation failed to demonstrate any lesion of the stomach or duodenum but a circumscribed induration was palpated in the body of the pancreas. A stone 1.75 cm in diameter was extracted. A post-operative roentgenogram disclosed a few more shadows in the region of the pancreas. The patient developed cachexia and expired 4 months after the operation. The stone contained carbonates and calcium but no oxalates or phosphorus, and gave a positive xanthoprotein reaction. Although stones in the pancreas may accompany arteriosclerosis, neoplasms, or syphilis, inflammatory processes propagated by contiguity or reaching the pancreas through the blood or lymph stream play the most important role in the production of stones

The author collected from the literature 74 cases of stones in the pancreas. In the majority of cases the stones are multiple and consist of calcium phosphate (80%), calcium carbonate (17%), and organic matter (3%). A latent and a painful form, with or without intermittent jaundice, may be differentiated. A transient or persistent glycosuria is found in many instances. The examination of feces usually reveals a disturbance of the function of the pancreas. If a generalized lithiasis or so-called petrification of the pancreas is found in roentgenograms, a conservative treatment is the method of choice. Otherwise the stones should be removed surgically

JOSEPH K. NARAT, M D

Splenomegaly, Splenic Arteriovenous Anastomosis, and Banti's Disease (Splenomegalia, anastomosi arteriovenose spleniche e malattia di Banti) PIETRO FRANCESCHINI *Sperimentale*, 1948, 99 1

In 1939 the author first described the existence of arteriovenous anastomosis in a spleen removed from a patient with Banti's disease. He thus established that the sinus apparatus is not the only communication between the arterial and venous system. The arteriovenous anastomosis allows for direct and rapid emptying of the arterial blood into the larger veins. This is the method which causes reduction of the size of the spleen when adrenalin is administered to the patient.

The author thus concludes that Banti's disease is caused by an irreversible disturbance in the functional cycle of the splenic sinuses, which results in a progressive enlargement of the spleen. This disorder is not relieved by ligation of the splenic artery and, hence, splenectomy remains the procedure of choice in the treatment of Banti's disease.

LUCIAN J. FRONDUTI, M D

On Splenectomy, with Special Reference to Indications H. ABRAHAMSEN and N. B. KRARUP *Acta med scand*, 1948, 131 Supp 213, p 9

This study of 45 splenectomized patients shows that the diagnoses considered to be indications for splenectomy are not always well defined pathologically but often cover more or less vague collective notions. In each case the primary diagnosis, the findings at operation, and the postoperative course of the disease have been studied in an attempt to clarify the diagnostic problems and indications for splenectomy. Uncertainty is especially conspicuous in the case of the diagnosis of Banti's disease.

There were 16 splenectomies based on the supposition that the patients presented Banti's disease. When a later examination took place only 4 of the group were alive, of these, 3 had been materially benefited, while the condition of 1 was unchanged. There were 4 deaths immediately after the operation, and 7 patients died from 3 months to 25 years after operation. A revision of the diagnoses on the basis of the postmortem findings and later examination leads to the conclusion that it would be most expedient not to use the diagnosis of Banti's disease in clinical work at all. In cases of splenomegaly with or without anemia the primary diagnostic task must be an attempt to reveal any specific disorder underlying the splenomegaly (leucosis, nonleukemic myeloid splenomegaly, lymphogranulomatosis, reticuloendotheliosis, Gaucher's disease, tumor, tuberculosis, or syphilis). If found, splenectomy will almost always be contraindicated. It will also be almost always contraindicated in the presence of liver cirrhosis. Splenectomy will be indicated for cryptogenic splenomegaly without liver involvement and for thrombosis of the splenic vein.

There were 12 patients splenectomized for hemolytic jaundice, in half of whom a hereditary factor was established. Splenectomy appeared to be the

treatment of choice in subacute and chronic cases, and was the treatment of necessity in acute, critical cases

A review of 6 cases of splenectomy for chronic essential thrombopenia showed that the effect of splenectomy was immediately good in all cases and of lasting benefit in all but 1 case

There were 4 patients operated on because of splenomegaly, the splenic enlargement affording the indication for operation, and 7 patients operated on because of ruptured spleen

JOHN L. LINDQUIST, M D

Splenectomy in Brucella Infection (La splenectomia nella infezione brucellare) GIUSEPPE GIUNCHI
Polisimico, sez med, 1948, 55 125

In 1 case of brucellosis resistant to vaccinothérapie, penicillin and sulfonamides were administered, but a cure was obtained by splenectomy. The weight of the removed spleen was 960 gm. The organ contained multiple hemorrhagic infarcts. Hepatomegaly and bilirubinemia subsided after the operation. Periodic clinical, bacteriologic, and serologic examinations during the first postoperative year failed to disclose any evidence of brucella infection.

In the second case complications in the form of a grave anemia, left orchitis, and painful limitation of motions of the left hip were present. The failure of conservative treatment suggested a more radical procedure. In view of the grave condition of the patient, instead of splenectomy a ligation of the splenic artery was performed. A large amount of hemorrhagic fluid was encountered in the peritoneal cavity. Within the first 10 postoperative days 18 more liters of similar fluid were withdrawn by paracentesis, repeated 3 times. Three years after the operation the patient was in perfect health.

In selected cases such operative procedures may supplement or replace the treatment of brucellosis with streptomycin alone or in combination with sulfonamides.

JOSEPH K. NARAT, M D

MISCELLANEOUS

The Traumatic Condition of the Abdomen ARTHUR R. METZ, RAYMOND HOUSEHOLDER, and GERRIT DANGREMOND *Am J Surg*, 1948, 76 368

Injuries to the intra-abdominal organs are not uncommon and usually are serious. Their successful management depends on early, accurate diagnosis followed by immediate intelligent treatment. An understanding of the anatomy of the abdominal area and the mechanism of injury, and a thorough routine of examination are essential in caring for the patient who has sustained trauma to the abdomen.

Distended organs are more liable to injury than empty ones, consequently, abdominal injuries are more likely to produce damage to the hollow viscera when sustained soon after the ingestion of food.

The most common causes of abdominal trauma are as follows: (1) direct violence, such as a blow to the abdomen by some blunt object, as a piece of wood or

a tool that the individual may be handling, (2) indirect violence as a fall from a height of a few feet or more, the impact of landing producing the injury, (3) nonpenetrating wounds, for example, squeezing injuries from pressure between moving objects, and (4) penetrating wounds such as from a stab or gunshot.

Success in managing cases of traumatic injuries to the abdomen may well depend on the primary examination of the patient and the recorded findings by the first attending physician. A thorough examination routine is helpful and should be combined with the taking of an accurate history concerning the injury.

An accurate history and description of the mechanism of the accident should be obtained to determine the amount of violence, distance of the fall, or any other facts that may be of value in determining the possible severity of the injury. The patient's reaction immediately following the accident should be ascertained—whether he noticed a sudden, sharp pain, whether he had to sit down or stop work for a short period of time, or whether loss of consciousness occurred immediately. Did the patient vomit and, if so, was blood present in the vomitus? Does the patient remember the details of the accident? This information may have an important bearing in helping to determine the extent of injury and in arriving at a diagnosis. In addition, it may be valuable for future reference as stories of accidents frequently change after time has elapsed.

When the patient is first seen, particular attention should be given to, and a record made of, the degree of shock, the volume and rate of the pulse, the blood pressure, temperature, and respiration. A blood count and urinalysis should be made. This gives the physician a basis for the status of the blood so that changes may be noted on frequent repeated counts. The presence or absence of blood in the urine is to be noted. It may be necessary to catheterize the patient to obtain a specimen.

The physical examination must be comprehensive. Roentgen films showing the entire abdomen, including the pelvis and lower chest, should be made.

The management and treatment of traumatic injuries of the several organs of the abdomen are presented in considerable detail.

Patients operated upon within the first 6 hours after a severe injury have better chances of recovery than those in whom surgery is delayed beyond the 6 hour period. In case of doubt it is safer to explore the abdomen than to delay surgical treatment too long as it may jeopardize the life of the patient.

JOHN E. KIRKPATRICK, M D

Two Cases of Enterogenous Cysts SVEN RÖKAEUS
Acta obst gyn scand, 1948, 28 113

The author reports 2 cases of enterogenous cysts, one from the Kronprinsessan Lovisa's Hospital for Children in Stockholm. One of the patients, a 25 year old woman, had a rectal cyst with symptoms not definitely related to the cyst. The other patient was a 6 weeks old boy without symptoms. Both of the

GYNECOLOGY

UTERUS

The Problem of the Presence of Sensitive Corpuscles of the Uterus (Sulla questione della presenza dei corpuscoli sensitivi dell'utero) NICOLA DAMIANI *Quad clin ostet gin*, 1948, 3 356

Keiffer described the presence of sensitive corpuscles in the myometrium and mucosa of the uterus. He enumerated 19 types in the myometrium and 2 or 3 in the mucosa. He also described a neuromuscular type of corpuscles as the most common one found near the cervix and in the proximity of the blood vessels.

The author failed to find any such structures in his histological studies and states that such sensitive corpuscles are the walls of arteries which have been cut obliquely, and that, physiologically, uterine sensation is so poor that it contradicts the existence of so many sensitive corpuscles.

JOSEPH M. A. PAPE, M.D.

Radiologic Diagnosis of Uterine Cancer (Diagnóstico radiológico del cáncer uterino) GONZALO ELIZONDO MARTEL *Arch cubanos cancerol*, 1948, 7 127

In 1,665 intrauterine hystero-grams for cancer there were no accidents. The uterus was filled gradually by the spot roentgen technique and the luteinic phase was chosen as the best time of the menstrual cycle for good diagnostic results.

The diagnosis is based upon uterine tonicity and contractility. In the premenopausal phase while follicular function is active a tumor is revealed by an increase in contractility similar to that seen when a foreign body is in the uterus. In large infiltrating tumors, contractility is not observed, but a globose relaxation of the entire organ may be seen. In the postmenopausal stage the uterus appears dormant under the filling and distends without resistance.

The presence of filling defects may be detected by direct semiologic studies. At first the deformity appears small, fixed, and irregular in outline. This disappears as the uterus balloons out. In carcinoma there is no erasure of these features.

Hystero-grams are considered of absolute value in the localization of a lesion but only of relative help in diagnosis. They are particularly useful in obtaining information concerning uterine depth, location for the biopsy, and differentiation between intrauterine and extrauterine tumors.

STEPHEN A. ZIEMAN, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

The Significance of Cystic Enlargement of the Ovary with Respect to Treatment IRVING L. FRANK *Med Clin N America*, 1948, 32 1611

The author discusses cystic enlargement of the ovary and states that these cystic collections arise

either by the obstructive accumulation of the secretions of normal cells, or from the secretions of liquefaction necrosis of neoplastic cells. Most cystic enlargements of the ovary are due to perversions of the follicle apparatus and are physiologic variants. They are usually 5 cm. or less in diameter and are classified as "non-neoplastic" or "physiologic" cysts of the ovary.

On gross examination it is seen that the ovarian enlargement is due to the presence of many cysts varying from buckshot to cherrystones in size, scattered through the parenchyma, and usually occurring bilaterally.

Microscopically, congestion, edema, and fibrosis of the stroma, and "cirrhosis" of the ovarian tunic is found.

The author states that the most common causes of cystic enlargement are (1) inflammation—usually acute bacterial inflammation, (2) mechanical factors, such as ovarian prolapse with passive congestion and edema, and (3) hormonal imbalance.

The differential diagnosis between non-neoplastic cysts and true cystomas is difficult, but in general non-neoplastic cysts are usually bilateral, many decrease in size with time, do not usually exceed 5 cm. in diameter, and produce minor menstrual disorders, while neoplastic cysts are usually unilateral, enlarge constantly, and do not affect the menstrual cycle.

Two rather constant symptoms are produced by the non-neoplastic cysts: bilateral deep and boring lower abdominal pain with radiation to the thighs and back, and menstrual disorders.

Treatment is varied, but, in general, observation with repeated pelvic examinations is all that is required, correction of uterine displacements and improvement of the pelvic circulation with pessaries and postural exercises, and the control of pelvic infection may be of value in many cases. Hormone therapy utilizing large doses of stilbestrol, as advocated by Karnaky, or testosterone may be considered.

In general, surgery is not indicated in the treatment of the non-neoplastic cysts and should be considered only when the ovarian dysfunction is profound and the structural ovarian changes are definite.

J. ROBERT WILLSON, M.D.

A Report of 2 Cases of Tumor of the Internal Theca of the Ovary (Relation de deux cas de tumeurs de la thèque interne de l'ovaire) L. GRÉGOIRE *Bruzelles méd*, 1948, 28 2227

Two patients had been subjected to total hysterectomy. The first, aged 57, had a uterine fibroma and a thecoma of the right ovary; the second, aged 61, had a uterus too large for her age, a fibroma of the left ovary, and a calcifying and degenerating (hyaline) thecoma of the right ovary. Both had more frequent bouts of hot flushes after the opera-

tion than before it, and the breasts of the first patient were decidedly enlarged for some time.

The 2 cases represent the 2 principal forms of thecoma: the cystic variety described by some authors being probably a sort of follicular or luteinic cyst. When the epithelioid zones are very important (first case), recalling the thecal tissue of the corpus luteum, the differential diagnosis from the insular and sarcomatoid form of tumor of the granulosa may offer some difficulty. The argyrophile reticulum exists only in tumors of the theca, in addition, the tumors of the granulosa present, here and there, zones of epithelial follicles with Call-Exner corpuscles. The fibrous form (second case) differs from ordinary fibroma by the presence of masses of epithelioid cells, by lipid overload of the cells, especially cholesterol, and by its hormonal action.

According to Greenhill's 1947 Year Book of Obstetrics and Gynecology, about 100 cases have been reported up till now. About 70 per cent occur after the menopause, mostly between the ages of 50 and 60. There has been no case before puberty and no coexistence with pregnancy. The youngest patient was 12 years of age, the oldest 92. The symptoms of hyperfolliculinemia are manifested by reactions of the receptor organs, especially the uterus, with more or less functional disturbances. Of 50 uteri of which the mucosa was studied, 38 were hyperplastic (32 after the menopause), 3 normal, 2 atrophic, 5 malignantly adenomatous, and 2 pregravidic (these should be classed as luteomas). Of 52 described uteri, 24 had a fibromyoma, 17 revealed diffuse hypertrophy of the myometrium and 5 adenomyosis, while 7 were normal and 4 subnormal. Mammary congestion has been noted in some cases, among them being 1 patient at the age of 92. Functional disturbances varied and were sometimes absent, hemorrhagic metropathy during sexual life, and cyclic or irregular bleeding after the menopause (73 per cent of the cases). There may be glandulocystic hyperplasia without hemorrhages as in the second case. Removal of the tumor has caused menopausal disturbances in patients who were far beyond the menopausal age. Only 3 of 82 cases have presented a malignant evolution. The metastases also have a hormonal action. Bilaterality of a solid tumor of the ovary suggests a malignant nature.

Treatment is essentially surgical and conservative in young women. In case of solid tumor, the other ovary should always be explored. The radio sensitivity of thecomas seems to be low.

RICHARD KEMEL, M.D.

Disgerminoma of the Ovary (Fl disgerminoma ovarii) J. M. BIRDYAL. *Peripartu obst.*, 1948, 5, 200.

The cellular elements of disgerminoma of the ovary are found in the testes and ovaries. This tumor has many synonyms. It is usually assumed that the structure of the organ has been invaded. It is a solid homogeneous tumor, frequently bilateral in occurrence. As it is histologically malignant it grows rapidly as a rule and once it breaks through

its capsule it invades all of the adjacent pelvic structures.

Fortunately, this tumor is rare. It occurs most often in young persons and histologic examination is necessary to determine its nature.

Treatment is surgical followed by roentgenotherapy.
STEPHEN A. ZIMAN, M.D.

Primary Carcinoma of the Fallopian Tube. A Clinical and Pathologic Study with Personal Contributions (Il carcinoma primitivo della salpinge uterina. Contributo personale e studio clinico ed anatomicopatologico) G. VALLI. *Ginecologia*, Torino, 1948, 14, 383.

After reviewing about 500 articles, the author writes a comprehensive monograph embracing all the aspects of primary carcinoma of the fallopian tube. His opinions are based on 2 personal cases and a detailed study of 51 acceptable cases derived from the literature.

It was found that this tumor occurs once in 10,000 gynecological patients, which is rare enough so that many gynecologists never see one. It is often confused with secondary carcinoma of the tube, which occurs 10 times more frequently than the primary type. Pain, vaginal discharge, and pelvic tumor are the most constant symptoms, but none of these is pathognomonic. The pain is usually colicky, sometimes violent, localized in the lower abdomen and occasionally radiating to one of the thighs. The discharge may be of any type and is in no way diagnostic, except that microscopic examination may reveal malignant cells, which, however, would not locate the lesion in the tube. The mass is rarely noticed by the patient, but is felt by the surgeon during pelvic examination. It may be tender and usually unilateral. Frequently it is disguised by a coexisting inflammatory process. At operation the carcinoma is usually overlooked because of associated fibroid or inflammatory masses. Pathologic examination generally reveals the tumor not to be of a high grade malignancy, but there is an exceptionally early infiltration of contiguous structures, possibly caused by expulsion of the cells from the narrow tube. The prognosis is grave, only an occasional patient survives 5 years.

The treatment of choice is panhysterectomy, preferably with dissection of the pelvic lymphatics. Unfortunately this is rarely done because the diagnosis is not made until the routine microscopic sections are examined. It is recommended that surgeons make a more careful examination of the diseased tissues at the operating table, and order frozen sections when in doubt.

One of the author's records consisted only of a pathologic report on the clinical record and patient had been lost during the war. The second case was that of a 38-year-old nulliparous female who gave a past history of untreated active tuberculosis, a miscarriage of a molarated fetus 10 years previously, and uterine myomata for 10 years. She had 10 months previous to the onset of symptoms and

physical findings consisted of intermittent, colicky, abdominal pain in the left lower quadrant radiating to the thigh, yellow, watery vaginal discharge not related to the episodes of pain, and bilateral tender tumefactions of the adnexa, interpreted by the examiner to be pelvic inflammatory disease. At operation there were found bilateral hydrosalpinx and numerous inflammatory pelvic adhesions. The specimen seemingly corroborated the clinical impression and led the operator to remove only the tubes. The pathologic report revealed a primary carcinoma of the left fallopian tube. Histologically the tumor was primarily glandular with papillary and alveolar aspects and was considered to be of high grade malignancy. At the time of writing, 2 years after the laparotomy, the patient was gravely ill from abdominal metastases, notwithstanding massive doses of deep roentgen therapy.

N. CHRISTIAN MEYER, M.D.

EXTERNAL GENITALIA

Two Cases of Vaginal Atresia Observed in Duplex Anomalies of the Genitalia KEIJO SOIVA *Ann chir gyn fenn*, 1948, 37, 276

The author observes that imperforation of one side of a double vagina is comparatively rare. Divergent opinions have been expressed as to the frequency of duplication of the genitalia. The literature on this subject is reviewed briefly by the author. One writer has found only 3 cases among 19,000 patients, whereas another found 10 such malformations among 7,400 patients.

There has been much controversy as to the causes of atresia in genital passages. In the earlier literature, they were unanimously considered to be of a congenital nature. In the opinion of more recent investigators, all imperforations found in otherwise normally developed genitalia are secondary phenomena, that is, cicatrices that appeared after birth due to inflammatory processes. This is also considered the cause of imperforation, at least in the majority of double anomalies of the genitalia. It is observed by the author that other more recent writers reviewed do not entirely exclude acquired atresia, although they believe that the majority of imperforations in double genital passages are congenital. The formation of cicatrices causing imperforation may develop after serious inflammations of the vagina, which in children can be due to gonorrhea, but which have sometimes been observed also in connection with scarlet fever, diphtheria, or pneumonia, or as a consequence of puerperal fever or febrile abortion.

After a brief presentation of the symptoms of vaginal atresia, the author discusses the diagnosis. Operative treatment alone is of help in these cases of vaginal atresia. The extent of the intervention must be carefully considered for each individual case. If there is an accumulation of blood or collection of pus confined to the vagina, only the removal of the septum dividing the vagina is done. If, on the other

hand, the accumulation of blood and pus extends or is believed to extend into the uterine cavity or into the fallopian tubes, a removal of the uterus and of the tube is generally advocated. Sometimes total extirpation of the uterus is necessary.

The author presents in detail 2 cases in which atresia was found in one of the double vaginas. In one of the cases, that of a girl of 15, the operation revealed a double uterus and an accumulation of blood in the left vagina, uterus, and fallopian tubes which had developed together with congenital atresia of the left vagina. The left uterus with its adnexa was removed and the hematocolpos directed into the right vagina. In the second case, a girl 9 years of age was found to have 2 narrow vaginas divided by a thin septum, in the upper part of which there was an imperforation with a collection of pus. The septum was removed. No portio uteri was found at the end of the vagina, nor was the uterus palpable in the internal examination.

HERBERT F. THURSTON, M.D.

MISCELLANEOUS

Newer Concepts of Menstruation IRWIN H. KAISER *Am J Obst*, 1948, 56, 1037

Bleeding is the most conspicuous feature of the menstrual process. Because of this, a large part of the laboratory and clinical study of menstruation has been directed toward the blood vessels of the endometrium. An explanation of the cyclic uterine bleeding as a consequence of alterations in the coiled arteries of the endometrium has gained widespread acceptance.

There are two basic interpretations of menstruation. A mechanical concept is based on the observation that the coiled arterioles increase rapidly in complexity and extent as the secretory phase of the cycle progresses. This increasing complexity reaches a point at which it impedes the flow of blood to the endometrium and produces ischemia, which then sets off the chain reaction of menstruation. A pharmacodynamic concept stems from the observation that prolonged periods of vasoconstriction are invariable precursors of other menstrual changes. The growth and differentiation of the coiled arterioles render them sensitive to the action of vasoconstrictor substances. These then produce vasoconstriction, ischemia, and menstruation. Both concepts assume that continued growth of a complex, coiled arteriole is a necessary precursor of menstruation. Such hypotheses often bypass or contradict the earlier work on hormone withdrawal as the common precursor of menstrual flow.

The erroneous conclusions based on this faulty vascular hypothesis of menstruation are demonstrated by the recent observations of arteriovenous anastomoses in human endometrium, the presence of relatively vast areas of coiled arteries during early pregnancy with the absence of bleeding, the occurrence of bleeding during an anovulatory cycle when the arteriolar bed is much simpler than that of true

menstruation, and the presence of menstruation in New World monkeys in the absence of coiled arteries

The current explanation of menstruation, based upon alterations of the coiled arterioles, fails to account for much that is known about the menstrual process. It appears that the coiled arteriole is of principal importance primarily in the process of implantation of the embryo. JOHN R. WOLFF, M.D.

Preliminary Results of Streptomycin Therapy in Tuberculosis of the Peritoneal Cavity and of the Adnexa in the Female (Primi risultati della terapia streptomycinica nella tubercolosi peritoneale—annessiale) EUCLIDE FORLINI *Quad clin ostet gni*, 1948, 3 424

Four cases of tuberculosis of the female genitalia, 2 of which were verified by laparotomy, were treated by the local and parenteral administration of streptomycin, accompanied by general medical therapy (rest and ultraviolet irradiation therapy, and the administration of vitamins A and D, and calcium thiolsulfate). In 2 instances the drug was administered into the residual ascitic fluid after part had been withdrawn, in the others the administration was entirely parenteral or by injection into the masses of adnexal tissues through the vaginal fornix. The dosages were never more than from 250 to 500 mgm per day.

In every case, after treatment of a few days to a few weeks the ascites disappeared, the abdomen became flaccid and painless, and the adnexal masses entirely disappeared. These patients were followed up for as long as 5 months after treatment, the fever had ceased and in every instance there seemed to be complete cure.

The author admits that his cases are few, that the tubercle bacillus was not demonstrated in any of the material withdrawn, and that the general therapeutic measures, including pretherapeutic laparotomy in 1 case, may have helped in the cure, and, finally, that complete cure was not proved in any of these patients, nevertheless, he believes that the results procured are sufficiently encouraging to indicate that the authorities should put streptomycin at the disposal of the gynecologist, as well as of the phthisiologist for purposes of trial in genital tuberculosis of the female. JOHN W. BRENNAN, M.D.

Observations on the Delay Period in the Diagnosis of Pelvic Cancer JOHN Y. HOWSON *Med Clin N America*, 1948, 32 1573

The author has reviewed 1,000 cases of pelvic cancer obtained from the files of the Committee for the Study of Pelvic Cancer in Philadelphia. In an analysis of the delay period it was found that there was a definite physician delay in 276, and a patient delay in 437 of the 1,000 cases. The greatest delay occurred in carcinoma of the vulva (27 months), and the shortest delay occurred in carcinoma of the cervix (from 7 to 8 months). The greatest factors in the physician delay were incorrect diagnosis and failure to examine the patient in the presence of pelvic

symptoms. The reasons offered for the failure to examine the symptomatic patients were presence of active vaginal bleeding, indiscriminate use of medication, failure to examine at first office visit, patient unprepared for pelvic examination, symptoms indicative of the menopause, and patient visited in the home.

In the examined case the delay was due to incomplete examination, incorrect diagnosis, or to wrong treatment following the making of the correct diagnosis.

The author concludes by stating that the early diagnosis of cancer can be facilitated only if the physician becomes more cancer conscious, and (1) examines all patients with pelvic complaints, (2) urges periodic examination of women over 40, (3) withholds treatment of pelvic complaints until diagnosis is made, (4) does pelvic examination at first office visit, (5) does complete examination, including use of the speculum, (6) examines patients who are actively bleeding, (7) refuses to treat patients who refuse examination, (8) studies suspicious cancer lesions relentlessly, (9) institutes proper therapy in the presence of known cancer, and (10) arranges for specific clinic or specialist care of cancer patients. J. ROBERT WILLSON, M.D.

Biological Significance of Protein Concentration and the Changes Occurring in Gynecologic Laparotomies (Importanza e significato biologico del patrimonio proteico dell'organismo e suo comportamento nelle laparotomizzate ginecologiche) MICHELE GIARDINELLI and CAMILLO ROSSO *Ginecologia*, Tor., 1948, 14 340

Determinations of proteins according to Phillips, and the Van Slyke method, of hematocrit values and of hemoglobin were made by the authors in 20 patients before and after laparotomies for obstetric or gynecologic conditions. All operations were performed under ether anesthesia.

The first 2 days after the operation the protein content of the blood serum, the hematocrit values, and the amount of hemoglobin rose. This increase undoubtedly was attributable to hemoconcentration.

Later on the hematocrit values and the amount of hemoglobin returned to their normal levels while hypoproteinemia was recorded in the majority of cases. As a rule, normal protein levels were reached toward the end of the first postoperative week.

During the pregnancy, especially in its terminal stages, the hematocrit values were found to be relatively low because of gestation hydremia.

Intravenous injections of protein hydrolysates proved very valuable in combating hypoproteinemia. JOSEPH K. NARAT, M.D.

On Sterility in Finnish Women with Special Reference to Its Causes and Prognosis ALLAN VEHILÄ and KARI *Acta obst gyn scand*, 1948, 28 Supp 5

In the introduction of this treatise the author defines sterility as meaning that no impregnation has occurred. Infertility denotes that fecundation of the

ovum has taken place but that its regular development has been interfered with. Theoretically, these definitions are exact, but in practice it is often exceedingly difficult to differentiate one condition from the other. Physiological sterility is not considered in this study, nor is voluntary childlessness by contraceptive practices. Of pathological sterility there are different forms. If conception does not take place in spite of regular married life continued for several years, the term primary sterility is used. Sterility is considered secondary when, after one or more pregnancies, a woman loses her capacity for conception. The object of the present study is to examine the causes and the prognosis of sterility on the basis of the material collected from Finland.

In this investigation, the author used the term "primarily sterile marriage" to denote a marriage which has lasted at least 3 years without the occurrence of conception. A marriage is considered "secondarily sterile" if at least 4 years have elapsed since the end of the last pregnancy.

It is not possible to divide sterility into two distinct elements, namely, that due to the male, and that due to the female factor. Therefore, although the principal object of the present investigation is to deal with the causes and prognosis of sterility in women, it also touches some questions associated with male sterility.

The methods of examination are discussed by the author. When treatment was begun the average age of the patients in the present series was 32.2 years—those with primary sterility, 31.7 years and those with secondary sterility, 33.1 years. The average period for which married women with primary sterility had remained childless was 6.3 years. The average time elapsed from the end of the last pregnancy was 6.4 years in the case of the secondarily sterile married women. The average duration of sterility in all of the cases was 6.3 years. More than half of the patients with primary sterility had passed the optimal period of fertility when they were married. Breipohl expressed the opinion that a late menarche and irregularities at the first menses are likely to be of importance for the evaluation of fertility. He regarded the sixteenth year of life as the critical age of menarche in this respect. In the series reported herewith, the author observed that the prognosis of sterility seemed less favorable as the menarche was delayed. This decline, however, was so slight that there was a statistical difference only between the cases belonging to the earliest and the latest group.

By way of presenting the etiology of sterility, the author gives a tabulation in which the present series is divided into 6 main groups. The first of these, in which the vaginal factors were responsible, represented 1.6 per cent of the whole series. The group resulting from uterine factors amounted to 4.3 per cent. The tubal factors represented 45.4 per cent, endometriosis 8.5 per cent, and genital insufficiency, 20.5 per cent. The miscellaneous and unknown factors were represented by the sixth group which amounted to 10.7 per cent of the whole series.

The second of the two main objects of the present study was to investigate the prognosis of sterility. For this purpose, questionnaires were sent to such patients of the present series as were not under constant supervision. This method supplied information on the subsequent condition of 1,417 patients over a period of from 3 months to about 10 years. There was no information available on 273 cases, or 16.2 per cent, of the cases. As a result of this questionnaire, it was learned that 25.6 per cent of all the patients had become pregnant. It is significant that all of the patients revealed a less favorable prognosis as the age at which treatment was started increased. The most marked fall in the present series occurred at 3 years, which suggests that it is well to begin the treatment of sterility before the limit of 3 years, especially if the patient is elderly.

In the final summary the author notes that the object of the investigation herewith reported was to study the etiology and prognosis of sterility in Finnish women. The study was based on a series of 1,690 cases of sterility, 1,095 of which were primary and 595 secondary.

The sperm of the husband was examined in 821 cases, in 113 of which (13.7 per cent) azoospermia was revealed. These 113 were excluded from the series when female sterility was considered. Physical examination alone was carried out in 473 cases, hysterosalpingography in addition to it in 614 cases, insufflation in 164 cases, hysterosalpingography and laparotomy in 207 cases, and laparotomy in 232 cases.

The patients came up for observation at the average age of 32.2 years. The average duration of sterility was 6.3 years. In the present series, contraception did not seem to affect notably the duration of sterility. In cases of primary sterility, the patients' average age at menarche, 14.7 years, corresponded to the results of investigations recently carried out in Finland regarding the age at the menarche. The prognosis of sterility seems to show only a slight decline as the age of menarche increases. Of the patients with primary sterility, 15.7 per cent showed cyclical lability and 6.9 per cent cyclical debility. In the cyclically labile, the prognosis of sterility did not differ from that of the whole series, while in the cyclically debile the prognosis was worse.

The series was divided into 6 main etiological groups. Vaginal factors figured in 27 cases, or 1.6 per cent, of the series, and uterine sterility in 73 cases, or 4.3 per cent of the series.

In the largest etiological group, that for tubal sterility, (768 cases, or 45.4 per cent, of the whole series) examination of tubal permeability revealed tubal factors in 47.4 per cent, and physical examination alone in 40.0 per cent. Tubal sterility was considered as due to ascending infection in 37.7 per cent of the whole series. Of these cases, 3.1 per cent were due to gonorrheal infection, 10.6 per cent to infection following abortion, 5.9 per cent to infection following labor, and 18 per cent to other ascending infections. Tubal changes due to appendicitis were regarded as

responsible for sterility in 18 per cent of the whole series. In the present series genital or peritoneal tuberculosis appeared as a factor leading to sterility in 12 per cent. "Salpingitis isthmica nodosa" was considered responsible for sterility in at least 13 per cent of the series. Other cases of tubal sterility, which could not be placed into any of these groups, constituted 34 per cent of the whole series.

Endometriosis externa intraperitonealis was the probable cause of sterility in 85 per cent of the present series (143 cases). The surgically treated cases of endometriosis constituted 255 per cent of all the laparotomies. Intramural and isthmic tubal occlusions, possibly due to endometriosis tubae, appeared to be relatively rare in patients suffering from endometriosis, for only 8 of the 56 salpingographically examined patients with endometriosis externa showed such occlusions.

Genital insufficiency was considered responsible for sterility in 295 per cent (498 patients) of the whole series, in 355 per cent of the patients with primary sterility and 183 per cent of those with secondary sterility. In 725 per cent of cases in this group (361 patients with primary sterility) primary genital insufficiency was considered present. The incidence of genital infantilism and that of genital hypoplasia seemed to be roughly equal. Secondary genital insufficiency was considered responsible for sterility in 221 per cent (1 patient with primary and 109 patients with secondary sterility) of this group. In the remaining 54 per cent (27 patients with primary sterility) this subgrouping was not found to be feasible.

The last etiological group, in which the sterility was due to miscellaneous and unknown factors,

constituted 107 per cent (181 patients) of the whole series. In this group, the 44 cases of posterior parametritis are worthy of mention.

Of all the patients in the present series, 256 per cent (432) became pregnant. The corresponding figure for the group with primary sterility was 256 per cent, and for those with secondary sterility, 255 per cent. In 254 per cent of those who became pregnant, treatment had lasted 2 years or more before pregnancy began. It was not until treatment had lasted more than 5 years that there was a marked fall in the favorable prognosis. This showed a steady decline as the age increased at which the patients were admitted for treatment. This decline associated with the lengthening of the period of sterility was most clearly seen at the 3 year limit.

Treatment in the two first etiological groups, (vaginal and uterine sterility) resulted in pregnancy in 45 per cent of the patients. In the group associated with tubal sterility, 132 per cent of the patients became pregnant, while 23 per cent of the patients with unilateral occlusion or impaired tubal patency, and 51 per cent of those with bilateral occlusion, became pregnant.

Of the patients with endometriosis, 329 per cent became pregnant. The prognosis in the secondarily sterile patients seemed to be better than that of the primarily sterile patients. In the group of patients with genital insufficiency, 311 per cent became pregnant.

Pregnancies occurred in 464 per cent of the women with sterility due to miscellaneous and unknown factors. Of the 44 patients with posterior parametritis, 26 became pregnant after treatment.

HERBERT F. THURSTON, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

An Ultimate Resort in the Diagnosis of Pregnancy
SVEN SJÖSTEDT *Acta obst gyn scand*, 1948, 28
167

At laparotomy the gynecologist is occasionally confronted with an enlarged uterus which may be pregnant when prior to surgery there was no reason to suspect pregnancy. When this situation arises the surgeon (1) may close the abdomen and verify the diagnosis, (2) inspect the ovaries, looking specifically for a corpus luteum of pregnancy, (3) roentgenograph the mass at the time of surgery, (4) aspirate the uterine mass with a needle, or (5), as advocated, make an exploratory incision in the uterus.

Five cases of uterine exploration through a small incision were reported by Hellsten in 1917. In 1 case a cystic myoma was diagnosed, in 2 instances pregnancy, in 1 case hydatidiform mole, and in the last case the findings were misinterpreted and a pregnant uterus was removed.

The author reports on 3 diagnoses in which uterine incision was carried out. In the first case pregnancy was diagnosed after the exploratory incision was made. Subsequent pregnancy tests and roentgenograms did not verify this diagnosis and laparotomy revealed a myoma undergoing cystic degeneration. In the second case pregnancy could not be verified and, at laparotomy with a uterine incision, placental tissue was found. The uterus was sutured and the abdomen closed, but shortly after discharge the patient was readmitted for abortion. The last case was that of a patient who on laparotomy was found to have an ovarian fibromyoma plus a uterus irregularly enlarged to the size of a 4 months' pregnancy. Uterine exploration revealed placental tissue and the uterus was closed. Five months later the patient delivered a boy weighing 4.3 kgm.

The uterine incision must be adequate, at least 5 cm. long and from 1.5 to 2 cm. deep, in the midline and on the anterior aspect of the uterus. The risks of this procedure are slight and injury to the amnion can usually be avoided. The author recommends the utilization of this procedure in troublesome and puzzling cases.

J. ROBERT WILLSON, M.D.

Two Cases of Pregnancy in Uterus Subseptus Unicorporeus and One Case in a Double Uterus (Dois casos de gravidez em útero subseptus unicorporeus e um em útero duplo) MARIA DOS SANTOS PINTO
Rev. Port. obst. ginec., 1948, 1: 341

One of the rarest congenital malformations of the female genital apparatus is uterus subseptus unicorporeus. In fact, the incidence of double formations increases with the height of the genital canal, double vaginas being rare, double uteri more frequent and bicornate uteri with a single cervix still more frequent.

The first case of uterus subseptus unicorporeus was observed in a woman of 22 years admitted during the ninth month of her pregnancy. Gynecologic examination revealed two vaginal orifices, the right one being the largest, and two noncommunicating vaginas, each with an independent softened cervix. The left fornix of the right vagina and the right fornix of the left vagina were smaller than those of the opposite sides. The right vagina easily allowed bigital examination, but penetration of two fingers into the left vagina was difficult. During labor the contractions were of good quality and the fetus was unaffected. After spontaneous rupture of the membranes the fetal head was engaged, the orifices of the two cervixes presented a dilatation of two fingerbreadths and the sutures and fontanels could be felt through each cervix. Under balsoforme anesthesia the vaginal septum was incised between two clamps, an incision was made uniting the two cervixes, and the living fetus was extracted with forceps after a unilateral episiotomy had been performed. The puerperium was normal.

In the second case of uterus subseptus unicorporeus, observed in a woman of 29 years, the septum was thick at its points of implantation in the vagina and thin in its middle portion, it ran anteroposteriorly and separated the two vaginas completely. The cervixes were partly flattened out but their dimensions, as well as those of the vaginas, did not allow delivery by the vaginal route. Therefore, low cesarean section was performed. A living child was obtained and the postoperative course was uneventful.

In the case of double uterus observed in another woman of 29 years, examination revealed that the vulva was divided by an anteroposterior septum and had two hymens, of which the left one presented no opening. The septum extended from the vulva to the uterus or uteri. The fundus of the left vagina presented a very small, softened cervix with nullipara orifice, and that of the right vagina a larger, softer cervix with the characteristics of a first pregnancy. In both fundi was felt a cephalic presentation which distended them. During labor the right cervix dilated and the left remained closed, the septum was displaced to the left but offered great resistance to the insinuation of the fetal head. When the cervix was completely dilated, the head was only slightly engaged and the fetus was suffering. Under spinal anesthesia the resistance of the septum was overcome by manual dilatation and a living child was extracted by forceps and the aid of an episiotomy. After delivery it was found that the septum had been torn in its entire length and also from the border of the cervixes. Repair left one cervix at the fundus of a single vagina.

The two cervixes gave access to two uterine cavities, one of which became pregnant, while the other increased slightly in volume. During labor the second

cervix underwent a beginning of dilatation and admitted one finger. In cases of double uterus the two cavities may become pregnant, but the pregnancy is then nearly always interrupted prematurely and the ova may be expelled at intervals of several months. Pains and bleeding may be observed, the first being due to uterine distention, the second to the hypertrophied decidua formed in the empty uterine cavity. If the wall of the pregnant uterine cavity has enough musculature, the pregnancy may go to term, otherwise, it ends in abortion or premature labor. The complications which may occur during labor in case of double uterus are due to the presentation, the modality of double uterus, the degree of elasticity and distention of the cervix and the vagina, and the degree of development of the uterine wall.

RICHARD KEMEL, M D

Extrauterine Pregnancy Exteriorized Through a Persistent Malpighi-Gartner Canal with Expulsion of Skeletal Remnants of the Embryo
(Gravidanza extrauterina estrinsecata attraverso un persistente canale di Malpighi Gartner con l'espulsione dei resti scheletrici dell'embrione) ICILIO PARDINI *Chim ostet*, 1948, 50: 188

A rare form of extrauterine pregnancy is the infra-ligamentary type in which the ovum settles in the tube and the placenta develops on the lower wall of the tube where the villi destroy the muscular bundles and gradually reach the connective tissue of the mesosalpinx and the broad ligament so that the ovum becomes implanted secondarily in the connective tissue of the pelvis. Pardini reports the following case:

A woman of 24 years had her last regular menstruation on July 4. On October 18 she suddenly experienced severe abdominal pain in the right lower quadrant, persisting for 2 or 3 days. On November 4 she had slight sacrolumbic pain and a small loss of blood from the vagina. After a few hours she expelled a piece of fleshy substance which looked like an empty sac. Hemorrhage and pain then stopped. On November 10 she again started to lose blood, which for the first day had the characteristics of a menstruation, but then became blackish and mixed with fetid purulent material.

Examination disclosed at 15 cm below and to the right of the urinary meatus a small opening from which issued the fetid blackish material. The uterus was of normal size and strongly displaced to the left. Through the right vaginal cul-de-sac could be felt a round mass, the size of an orange, nonmobile, in direct contact with the right side of the cervix and partially in front of it. The lower pole of the mass was in broad contact with the vaginal vault. A probe introduced into the orifice below the meatus was passed upward and slightly to the right, reaching the lower pole of the lateral mass. Vaginal palpation revealed under the mucosa a fibrous cord which ran to the right of the urethra, first upward and laterally, then straight ahead to be lost in the fornix close to and in front of the cervix. Iodoform was injected through

the orifice and the film showed that this canal communicated with the paracervical mass.

Two days later the orifice was occupied by a blackish, small foreign body which proved to be of an embryo, then other bones were easily extruded from the canalicule and many were found in the dressing during the following 4 days. The mass then became grayish, mucous, and gradually disappeared, while the mass was reduced to the size of a pigeon's egg, but the canalicule persisted throughout the entire course.

There is no doubt that the presence of the canal was due to the persistence of a Malpighi-Gartner canal. This was demonstrated by its course posterior to the urethra, its fibrous consistency, and the fact that no other organ can be present at this site during the embryonic stage and in adult life.

The death of the ovum could have occurred at different periods in the history of the case: at the time of the severe abdominal pain and at that of the expulsion of the decidua. The first would correspond to a pregnancy of 3.5 months, the second to one of exactly 4 months. Comparison of the collected material with those of embryos in the anatomic museum of Pisa showed that they resembled more those of embryos of the fourth month, therefore, the interruption of the pregnancy must have coincided with the expulsion of the decidua.

Pardini advances the theory that the ovum is implanted in the mesosalpingeal part of the ampulla, after perforating the tubal wall, it is situated between the leaves of the broad ligament, approached the side of the uterus so as to come in contact with the canal of Malpighi. At this point, for reasons which cannot be determined but which are probably connected with defects in the blood supply, the pregnancy was interrupted and found the way to the outside to be through the canal.

RICHARD KEMEL, M D

The High Occipital Position (Der hohe Geradenstand des Kopfes) YNGVE MONTELL *Ann chir gyn fern* 1947, 250

One of the rarest abnormalities of position at birth is the high occipital position. In the material of the Women's Clinic of the University of Helsinki which comprised 68,584 births between 1890 and 1945, there were only 80 cases, or 0.11 per cent of this type. The percentage of such cases in the years varied from 0 to 0.30. However, there is no doubt that the percentage of such cases is actually much higher and that many cases are overlooked because of the presence of complications of labor. Among the etiologic factors the most important are the forward inclination of the pelvis, the size of the fetus, the form of its head (flat roof of the skull), probably the time of rupture of the membrane. In addition there are many incidental causes such as malposition and a number of unknown factors. In many cases several factors are present simultaneously.

Two forms of high occipital position are distinguished: the pubic, in which the back of the

head lies behind the symphysis, and the sacral, in which it lies in front of the promontorium. Most investigators accept the pubic form as more common, the proportion of 3 to 1. In the present material, the sacral form was more frequent than the pubic form, the proportion being 2 to 1 (54 sacral cases as against 26 pubic). However, since spontaneous delivery occurred more often in the pubic form, the author thinks that in reality both forms are present with equal frequency. Although labor in the pubic form was somewhat longer than in the sacral, he considers the pubic form as more advantageous, not only because spontaneous births are more frequent but also because in eventual complications a low or semi-low forceps can ordinarily be used.

The treatment of high occipital position does not actually differ from that of other positions. If there is great disproportion, cesarean section is performed; otherwise, spontaneous birth is awaited. Of the 54 sacral cases, 21 (38.89 per cent) ended in spontaneous birth, 20 (37.03 per cent) in delivery by forceps, and 13 (24.08 per cent) in delivery by cesarean section. Of the 26 pubic cases, 11 (42.31 per cent) ended in spontaneous birth, 7 (26.92 per cent) in delivery by forceps, and 8 (30.77 per cent) in delivery by cesarean section.

In the sacral cases, 20 children (37.04 per cent) were born with the dorso-posterior position of the head, 19 (35.18 per cent) with the dorso-anterior position, and in the remaining 15 the position of the head was unknown. Of the 20 with the dorso-posterior position of the head, 11 (55 per cent) were born spontaneously. According to the literature, spontaneous birth of children in sacral cases occurs nearly exclusively in the dorso-anterior position of the head, i.e., the head rotates 180 degrees during birth. The position of the head was corrected in 2 cases although attempts at correction usually fail.

In spontaneous delivery of primiparas, labor was prolonged for both forms. In the pubic form it lasted 32.5 hours (31 for the first phase and 1 for the second phase), in the sacral form it lasted 29.3 hours (26 for the first phase and 3.3 for the second phase). There were no maternal deaths and only 2 (2.5 per cent) among the children.

RICHARD KEMEL, M.D.

Diethylstilbestrol in the Prevention and Treatment of Complications of Pregnancy

O. WATKINS
SMITH, *Am J Obst*, 1948, 56: 821

This study of the clinical evaluation of diethylstilbestrol therapy in human pregnancy is based on the analysis of 632 pregnant patients treated by 117 obstetricians according to the recommendations of the author as to the dosage schedule. These patients included ward and private patients and as to their residence represented a cross section of the United States with its varied climatic conditions, dietary variations, geographic distribution, and general obstetric care.

The basis for the use of this drug is that, in the dosage prescribed, stilbestrol has the ability to stimulate a greater production of the placental

steroid hormones and thus increase progesterone metabolism.

Therefore, stilbestrol should prove beneficial in any abnormal situation of pregnancy in which progesterone deficiency may be etiologically involved, provided the cells which secrete the steroid hormones are still capable of functioning. That progesterone deficiency might result in abortion and premature delivery has been established. It has also been shown that a progressive deficiency of the steroid hormones invariably precedes the onset of late pregnancy toxemia, eclampsia, and intrauterine death. A reciprocal relation exists between the vascular supply to the placenta and the circulating level of the steroid hormones. By combating a deficiency of estrogen and progesterone, vascular damage might be prevented, so that hormonal therapy might be of value in twin pregnancy, essential hypertension, and in the prevention of vascular complications. The use of stilbestrol for the treatment of late pregnancy toxemia, as opposed to its prophylactic use, is not advised since the vascular damage is already so advanced that the increased secretion of progesterone cannot be stimulated.

The dosage schedule is that of 5 mgm daily by mouth started during the sixth or seventh week. It is increased by 5 mgm at 2 week intervals to the fifteenth week when 25 mgm are given daily. The daily dosage is then increased by 5 mgm at weekly intervals. The drug is discontinued at the thirty-fifth week. For the prevention of late pregnancy accidents stilbestrol is started not later than between the sixteenth and nineteenth weeks. The initial dose is always the one for the particular week of pregnancy when therapy is begun.

Of 491 patients treated for bleeding between the sixth and twenty-first weeks of gestation (threatened abortion and abortion prophylaxis) 78 per cent carried to the twenty-eighth week, and 72 per cent had living babies. In 127 patients who had from 2 to 5 consecutive abortions prior to therapy the fetal salvage was 77 per cent.

For the patients with late pregnancy complications (24) this report is of a preliminary nature. The author believes that this prophylactic treatment has reduced the incidence of complications associated with deficiencies of the steroid hormones.

Only 9 patients (1.4%) reported toxic reactions such as nausea, headache, vaginal discharge, and skin rash.

JOHN R. WOLFF, M.D.

Acute Operative Intestinal Complications in Connection with Pregnancy

HANNES SAURAMO
Acta obst gyn scand, 1948, 28: 150

From 1921 to 1947, 8 patients suffering with acute operative intestinal complications associated with pregnancy were observed at the Womens Clinics 1 and 3 at the University of Helsinki. The incidence was 0.01 per cent. The author reviewed these cases thoroughly and found that the etiological factors were strangulation plus adhesions, strangulation plus Meckel's diverticulum, strangulation plus a

GENITOURINARY SURGERY

ADRENAL, KIDNEY, AND URETER

Studies on Backflow in Excretion Urography OLLE OLSSON *Acta radiol*, Stockh, 1948, Supp 70

At an early date, anatomists observed that material injected into the ureter escaped through the vena renalis. The first mention of this phenomenon to be found in the literature seemed to be that made by Gigon in 1856. With the introduction of retrograde pyelography (1906) the anatomical reconstruction method was reproduced clinically, whereby the phenomenon won clinical significance. In reviewing the experimental work reported in the literature Olsson states that, even in retrograde pyelography, this important and interesting phenomenon peculiar to backflow has not been sufficiently investigated.

In contrast to the amount of literature on the subject of backflow manifested in retrograde pyelography, the published reports of backflow discerned in excretion urography are but scanty. In an extensive material study, greater than any previously published study, the author elucidates certain questions bearing on backflow, especially in association with excretion urography. A description of the roentgenological anatomy of different types of backflow, their development and frequency in urographic material, is given.

The clinical material consisted of 100 intravenous urographic examinations exhibiting backflow. The examination technique adopted was that suggested by Hellmer, a description of which was published in 1943.

These cases of backflow were discovered by the author while perusing 1,500 urograms chosen at random for purposes of elucidation of the frequency of backflow in his material of excretory urograms.

The only mention of the frequency of backflow in excretion urography is that made by Lindbom (1943). In a perusal of 2,600 urograms, 15 cases of backflow (16%) were found among 900 cases in which ureteral compression had been applied. Among the author's 998 cases in which ureteral compression had been applied, the backflow phenomenon was exhibited in 25 per cent. In excretion urography with ureteral compression the visualization of backflow is by no means a rare phenomenon. In 98 of 100 urographic examinations, extravasation did not occur until after the application of very careful and prolonged ureteral compression.

Of greatest interest are the type and course of individual cases of backflow. These cases fall into two distinct groups: (1) the extravasate has the form of streaks or lines extending more or less regularly and medially from the kidney towards the spine, (2) the radiopaque extravasate is localized immediately adjacent to one or more calyces, from where it spreads in the sinus renalis around the renal

pelvis and its branches, and possibly out through the hilus. This group comprises 89 of the 100 cases under discussion.

The force with which the extravasate spreads in the course of excretion urography may be in most cases but little. In some cases the active contraction of the renal pelvis may now and then be assumed. Such a contraction of the renal pelvis may give rise to an abrupt increase in the intrapelvic pressure as well as to a change in the form of the fornix calyces which become more acute. Such a change favors the development of backflow.

With a view of ascertaining to what degree the designation of the term "pyelovenous" was justified, the author by experimental examination concluded that (1) backflow appearing in the radiograms as small fornix extravasates have no connection with the circulatory system, (2) backflow of the types most commonly observed in excretion urography is limited to the sinus renalis and does not involve in "injection" of urine into the circulation, (3) under vital conditions the tendency of the extravasate to spread to the blood vessel is less than in postmortem specimens, and (4) the term "pyelovenous backflow" for the designation of small sinus extravasate is not motivated.

The author suggests that on the basis of a thorough knowledge of the roentgenological anatomy, the various types of backflow should be designated

solitary	} rupture with	little	} overflow	
multiple		medium		sinus extra-
general		profuse		vasate

The clinical significance of backflow was considered by Olsson from the viewpoint of demonstrating how particular pathological conditions have a tendency to produce backflow, and to ascertain whether clinical changes can be brought about by backflow.

Distention of the renal pelvis is a condition that is necessary for the development of backflow. The author cites the case of an expansive process associated with a kidney tumor in which backflow was present. This phenomenon may be of differential diagnostic significance in renal tuberculosis and in acute renal colic as well as in kidney tumor.

The author reported 6 cases in which large radiopaque extravasates were discernible during the course of acute urography. These patients were examined very shortly after the onset of colic and the urogram was performed during the acute attack of pain, without any preparation of the patient.

The significance of backflow in this type of case from a roentgenological point of view is purely diagnostic, but from a physiopathological point of view the condition constitutes a sign of gross decompensation between the outflow of urine and the increase in intrapelvic pressure that exists during an acute

phase of renal colic. The contrast backflow begins so early that there is reason to believe it has already existed prior to the urographic examination. From his observations the author concluded that backflow, even profuse backflow, may occur in association with acute renal colic, and this backflow may constitute an integral part of the picture clinically, physiopathologically, and diagnostically.

The most common type of backflow observed in the course of excretion urography is the small sinusoidal extravasate. The type of backflow in which filling of the lymph channels and venous vessels may be visualized roentgenographically is relatively rare.

Experiments have shown that no short circuit exists between urine and blood in backflow of the type most common in excretion urography. Backflow should be termed according to its roentgen-anatomical extension, for example, fornix-sinus backflow, sinus lymph channel backflow, etc. The greatest significance of backflow is its diagnostic and differential diagnostic value in conditions such as tuberculosis, renal rupture, renal tumor, and acute renal colic.

CONRAD A. KUEHN, M.D.

The Indications and Results of X-ray Examination in Trauma of the Kidney (Les résultats et les indications des explorations uro-radiologiques dans les traumatismes des reins) TRUC and BRINGER *J urol méd*, Par., 1948, 54, 305

The clinical diagnosis of renal contusions and, in particular, severe ones does not offer great difficulty. The symptomatic triad of the general physical condition along with the urinary and local findings are sufficiently characteristic to establish the diagnosis. But in slight traumas or those of medium severity, it is not always possible to determine with certainty if there is a renal lesion, and it is also difficult to determine the extent of the renal damage.

Urologic examination does not always provide information of value. If cystoscopic examination can be carried out, the site of the bloody urinary ejaculations can be determined. Sometimes it is impossible to do this immediately after trauma because the patient is in shock.

Roentgenological examination permits the exact evaluation of the renal trauma. The only contraindication to this procedure is the severity of the trauma and the state of shock of the patient. When the trauma involves the kidney structure, immediate surgical intervention may be necessary. All injuries of the kidney should be studied from hour to hour and a roentgenological examination should always be made.

A flat film of the kidney region will demonstrate the renal silhouette or perhaps widening of the renal shadow. There may be a deformity or absence of the psoas shadow. The absence of motility of the kidney and the excursions of the diaphragm can also be shown. Associated lesions, such as fractures of the ribs, are readily demonstrated. These findings are not pathognomonic of trauma of the kidney, but they do have clinical significance.

The flat x-ray picture sometimes reveals stones that have not previously been suspected. The author cited a case of a 250 pound man who suffered a contusion to the right kidney region. He became anuric. Examination on the third day of the anuria showed a shadow that suggested a ureteral stone. After ureteral catheterization and relief of ureteral spasm by infiltration of the renal pedicle with novocain, there was a copious diuresis. Two small ureteral stones were then evacuated.

Retrograde pyelography in renal rupture may or may not be advisable, for it may aggravate hemorrhage or produce severe secondary hemorrhage. Infection may also be introduced into the kidney, and diffusion of the contrast media through the injured kidney may carry with it infectious organisms.

From many articles and numerous observations, it has been established that precise information from intravenous pyelograms has been obtained without infection or without initiation of secondary hemorrhage.

A retrograde pyelogram furnishes exact information and at times it is superior to that of the intravenous method. By the observation of strict aseptic technique, the danger of infection in retrograde pyelography is reduced to a minimum, but the risk still exists. The second objection to retrograde pyelography is the possibility of recurrence of a severe secondary hemorrhage that may be the direct result of the examination. The author stated that while the retrograde pyelograms give valuable information in early cases of renal trauma, the results are subordinate to those obtained by intravenous urography. If the renal trauma does not necessitate surgical intervention, and if the lesion heals with cicatrization, ascending pyelography after healing takes place may give useful and definite information as to the condition of the previously injured structures. Pyelograms made at this time may be useful too from a medicolegal point of view.

The intravenous pyelogram shows the physiology of the kidney and, at the same time, the renal function. If the information given by the intravenous method is not complete, it must be supplemented by the retrograde method, but it can satisfy the urologist concerning the condition of the injured patient and at the same time give information as to the existing morphology and pathology of the kidney.

Elimination by the injured kidney of the opaque substance presents certain advantages. It does not further traumatize the kidney and does not mobilize the clots that distend the fissures, neither does it aggravate the lesion or lead to infectious accidents.

In renal trauma intravenous urography permits a determination of the extent of the kidney lesion and helps to evaluate its severity. In certain cases it gives information concerning the renal parenchyma and the urinary passages. Insufficient blood supply may cause a poor excretion of the contrast media, or even the total lack of excretion on the contused side. If this is the case, early retrograde studies are indicated when the patient is no longer in shock.

When there is a recurrence of the hemorrhage accompanied by signs of severe blood loss and the hemorrhage is progressive in character, immediate lumbotomy is indicated. This operation allows for the suture of the ruptured kidney or, if necessary, a nephrectomy may be done if the renal parenchyma is injured beyond repair.

In case of severe injury, a flat x-ray film of the kidney, ureter, and bladder should be taken and an immediate intravenous urogram made at the same time. This x-ray examination will demonstrate the absence of trauma or the extent of trauma that is present. In cases of nonelimination of the contrast media by the contused kidney, the preoperative retrograde pyelogram gives valuable information.

If the patient is not in shock, he should be closely observed (temperature, pulse, blood pressure, condition of the lumbar fossa, and blood count). Cystoscopic examination may determine which side the blood is coming from, and whether the injury is minimal or both sides are involved, early intravenous urography gives a complete picture showing the functional state of the uninjured kidney and the condition of the injured kidney as well. It is possible to make a diagnosis whether the lesion is limited to the renal parenchyma, the pelvis, or whether the capsule is involved along with the pelvis and the calyces. The author makes a retrograde pyelogram if the intravenous urograms do not show elimination by the contused kidney.

The author concludes that roentgenography of the urinary tract and venous urography are indispensable in the examination of those patients who have suffered lumbar trauma. If the intravenous urograms show only diminished elimination of the opaque media on the contused side or there exists a slight alteration of one of the calyces, the patient usually recovers without surgical intervention. If the urogram shows a perirenal hematoma on the contused side, surgical intervention should be used only if it becomes absolutely necessary, otherwise, the treatment should be conservative. If the intravenous pyelogram shows no elimination of the radiopaque substance on the contused side, retrograde pyelography may give exact information as to the condition of the kidney. Surgical intervention in this type of case may be necessary. In case of very severe hematuria with perirenal hematoma which is progressive in character, the clinical signs determine the course to follow. In cases of renal contusions that are healed by conservation of the kidney, the intravenous and retrograde pyelograms give information concerning the secretory, excretory passages, and the morphology of the kidney. This procedure will also give valuable information in medicolegal cases.

CONRAD A. KUEHN, M.D.

Intravenous Urography and Retrograde Pyelography in Subcutaneous Injuries of Kidney A. STEINBOCK *Ann chir gyn fenn*, 1948, 37 Supp 4

Steinbock reported on the results of excretory and retrograde urographic examinations of 37 fresh cases

of, and 54 cases of old recoveries from, renal rupture. Intravenous urography may be resorted to early after injury provided the patient's general status permits it, positive findings render retrograde pyelography unnecessary. The latter may be performed in urgent cases prior to operation if operative intervention is decided upon on the basis of the clinical symptoms.

Intravenous urography is considered a harmless diagnostic procedure. It significantly establishes the existence and function of the opposite kidney, thus preventing the fatal removal of a solitary kidney. Two instances of solitary kidney were encountered among the author's 37 cases of fresh renal trauma. In 13 of these 37 cases the pyelogram was normal, filling deficiencies and intrarenal injury, each, were encountered 5 times and the contrast medium diffused perirenally 11 times. The causes of error in intravenous urography for fresh renal trauma are meteorism, blood clots in the renal pelvis, a sudden fall of the blood pressure, and shock. Shock usually contraindicates excretory urography.

Steinbock believes that retrograde pyelography requires perfect asepsis and slow injection, which may be advantageously followed fluoroscopically. He has never observed any harm from retrograde pyelography performed under aseptic conditions.

The foregoing diagnostic procedures are of great value, but are not absolutely decisive in determining the indications for operation. As a rule a fresh renal rupture seldom requires surgical intervention. Of the 37 patients only 4 were operated upon (2 nephrectomies, 1 pseudohydronephrosis incision, and 1 hydronephrosis suture were performed).

Fifty-four patients were examined several years after the occurrence of renal trauma. The pyelogram was normal in 40 of these patients, including 1 patient with rupture of the kidney and pelvis which had been sutured.

The article is concluded with a comprehensive bibliography and a short report of a case of incomplete rupture of the wall of a ureter. In the region of the ureteral tear there occurred extravasation of urine forming a large mass. In this instance excretory urography performed 3 days after the trauma failed to reveal the lesion because of the absence of renal excretion of the contrast medium on the injured side. However, retrograde urography performed 3 days later showed the site of ureteral rupture.

ROBERT TURELL, M.D.

Diagnostic and Therapeutic Considerations of Horseshoe Kidney (Riñon en herradura. Consideraciones diagnósticas y terapéuticas) A. E. GARCÍA, A. ROCCHI, J. CASAL, and A. I. GUÍNEA *Rev argent urol*, 1948, 17 133

Eight cases of horseshoe kidney are presented, a percentage occurrence of 4.745 over an 8 year period of urologic service at the Hospital Espanol. Four of the patients were treated surgically.

The so-called pathognomonic symptoms were observed in only 1 instance, for which reason it is be

lieved that the classic syndrome of horseshoe kidney is less frequent in occurrence and by itself does not justify a diagnosis. Urography is considered the most important single fundamental step in diagnosis. Treatment must be based on two factors, the pathologic process in the isthmus and the associated kidney lesions.

STEPHEN A. ZIEMAN, M.D.

Kidney Tumors (Tumores do rim) GUERREIRO DE FARIA *Hospital*, Rio, 1948, 34 699

The histopathology, diagnosis, and therapy of kidney tumors are discussed by the author. Numerous photographs and photomicrograms illustrate the article. The following classification of kidney tumors is offered by the author:

- 1 Tumors of the renal parenchyma
 - a Epithelial tumors: adenoma, carcinoma
 - b Tumors of the connective tissue: benign, such as lipoma, fibroma, and myoma, and malignant, sarcoma
 - c Embryonal tumors: benign, dermoid, malignant, dysembryoma (Wilms tumor)
 - d Tumors of the suprarenal gland: hypernephroma or Grawitz tumor
- 2 Tumors of the renal pelvis
 - a Epithelial: benign, papilloma, malignant, carcinoma
 - b Tumors of connective tissue: benign, lipoma, fibroma, and myxoma, malignant, sarcoma

The author advocates postoperative x-ray treatment, which is also indicated for palliation in cases in which a surgical procedure is contraindicated.

JOSEPH K. NARAT, M.D.

Injury of the Vena Cava during Nephrectomy (Blessure de la veine cave pendant la néphrectomie) A. PUIGVERT GORRO *J. urol. méd.*, Par., 1948, 54 349

Among the many accidents one sees that occur during nephrectomy, without doubt, the most dramatic is the accidental opening of the inferior vena cava by a sharp cutting instrument or laceration by traction on another vein. This serious accident fortunately is rare; one sees it chiefly on extirpation of the right kidney. The author stated that twice he has been the actor in this dramatic event.

The first case of operative injury to the vena cava was reported by Lucke in 1880 (a nephrectomy for sarcoma, through a transperitoneal approach). Lucke was able to place ligatures on the lateral wall of the vena cava and he packed a tamponade into the lumbar fossa. The patient died on the fourth day of uremia. The autopsy showed that the wound of the vena cava was an opening about a centimeter in length, and that it had been occluded by compression since the ligatures of catgut that he had thought to be in place over the opening in the vein were fixed in the vicinity without occlusion of the vessel.

In 1892 Schede for the first time performed a lateral suture of the inferior vena cava with success, but his patient died of cancer 15 days after operation.

In 1893 Marconi, assistant to Professor Bottini, published the report of a case in which the inferior

vena cava was sectioned, and in spite of this healing of the vein below the origin of the renal vein was obtained. Bottini marked a step in the history of venous surgery, for he proved experimentally that animals could survive following total ligation of the inferior vena cava at a level that was compatible with life.

Houzel in 1901 performed the first voluntary ligation of the vena cava during the course of nephrectomy. It was then learned that patients could survive this serious accident of ligation of the inferior vena cava.

While some authors obtain success by tamponage of the injured veins, others place hemostats to occlude the opening. A few surgeons practice lateral ligation of the vessel wall while others ligate the vein. However, most of these cases are handled by lateral suture of the vena cava.

While opening of the vena cava is usually accidental, in some cases—as that of Zoege von Manteuffel—the vein was deliberately opened. The author audaciously opened the vein about 10 cm. to extract an extension of the neoplastic growth that had its origin in the kidney. He sutured the wall of the vena cava and the patient recovered.

Opening of the vena cava is usually accidental and occurs during the enucleation of an enlarged kidney with marked perirenal and perihilar adhesions. It is on freeing these adhesions and dissecting the hilar glands in order to facilitate the dissection that openings into the vena cava or the renal vein, as it emerges from the vena cava, are produced.

In some cases the injury is produced by tearing an enlarged kidney or by tearing the pedicle when traction is put on a large pedicle to elevate the kidney. Some injuries occur during clamping of the pedicle, and in other cases there is so much stretching of the elastic wall of the vena cava with subsequent slipping of the ligature that the vena cava is opened.

In the author's first case, that of a calculous right kidney that was bound down by dense adhesions producing a block of fibrosclerotic tissue, he encountered great difficulty in freeing the pedicle. Preliminary liberation of the ureter from the lumbar fossa was attempted in order to approach the vascular pedicle. During this manipulation of the kidney, the vena cava was torn. A lateral opening 1 cm. in length was made. The bleeding was very severe and the operative field was immediately inundated with blood. A large pack was maintained for several minutes, and when the pack was being removed the hole in the lateral wall of the vessel was seen and two clamps were placed on the wall so as to form a V. In this way, he obtained hemostasis. Then the kidney was removed. Because of the elasticity of the vena cava and the small size of the hole, the lateral wall was sutured below the two previously placed hemostats.

In the second case the patient had a large congenital hydronephrosis. Following the manipulation and freeing of this large sac that was adherent to the lateral border of the vena cava, the wall of the vessel was opened and a gush of venous blood occurred.

The accident was extremely hazardous, and instantly the operative field was inundated with blood. Compression by a gauze pack was established. When the gauze pack was slowly raised, the surgeon saw the longitudinal hole in the vena cava which was immediately closed by two hemostats. Because of the good result obtained by ligation in the previous case, it was thought advisable to close the rent. This was possible after a first vain attempt was made. He protected the suture line with a gauze pack and proceeded with the extirpation of the kidney. The patient had an uneventful convalescence as if the accident had not occurred. Catgut ligatures were used in both cases.

When injury to the vena cava is controlled by clamping, lateral ligation, suture of the vein, or tamponade, the level of the injury is not of importance. But when the vena cava must be ligated to control hemorrhage, the ligation must be placed below the opposite renal vein, for the great anastomosis of the efferent system of perirenal veins, the reno-azygos-lumbar venous system, provides the return circulation of the remaining kidney. The experience of many surgeons has shown that death occurs when the ligation is placed above the renal veins of the remaining kidney. On the contrary, when the ligation is placed below the renal veins of the remaining kidney, this procedure is well tolerated, and the circulation is re-established by the azygos veins, by the extrarachidic system of veins, by the venous anastomosis of the abdominal wall as well as by the spermatic or ovarian veins.

Lumbar packing has been used with success in some cases. Colombino removed a tamponade 6 days after the operation and obtained healing. Many authors believe that clamping of the vena cava and packing are the methods of choice when lateral ligation of the wound is impossible.

Cabot utilized a hemostatic clamp in 1 case and left it in place for 7 days. Gayt considered that subsequent thrombosis occurred with the same frequency when the hemostatic clamp was correctly placed, as when the suture method was used.

Pasteau considered that suture for the repair of injury to the vena cava was the best procedure. He considered packing an uncertain method of hemostatic control. Clamping of the venous wound was a rapid and usually easy procedure if the clamps were well placed. From his experience Pasteau believed that the clamps should be left in place for 4 days following surgery, and when this was done he obtained excellent results. In spite of the opinion held by Pasteau, some authors do not fully agree with him, but they believe that clamping of the opening in the vena cava is rather a method of necessity imposed by the attenuating circumstances.

In summary, the author uses gauze packing with pressure against the opening in the inferior vena cava from 5 to 7 minutes. By carefully removing the pack, the tear in the lateral wall of the vein may be seen quickly and clamps without teeth can be applied. He advises that clamps be applied in a V

position, then the injury can be repaired with either fine intestinal type catgut or linen sutures. It is prudent to leave a gauze wick in contact with the venous opening to provide a means of controlling the return of the blood flow or as a hemostatic tamponade.

CONRAD A. KUEHN, M.D.

Ureterointestinal Implantation and Total Cystectomy for Cancer (*L'implantation urétéro-intestinale et la cystectomie totale pour cancer*) HENRI GODARD. *J. urol. méd.,* Par., 1948, 54, 313.

In the past years ureterointestinal implantation has benefited by numerous improvements, the work of the American surgeons, Coffey, Higgins, Hinman, Poth, Mayo, and others.

In spite of undisputed progress, the technique of operation is not completely standardized since there are at least three modifications of the Coffey method in addition to other techniques published in the literature from abroad.

The choice of operation for cancer of the bladder is made after evaluating the patient's general health, the local pathology, and the personal preference of the surgeon.

The opponents of ureterointestinal implantation base their opinion upon the hazards of surgical intervention (peritonitis and ileus) and the renal complications of postoperative suppurative (pyelonephritis and pyelonephrosis). However, urologic surgeons believe that there will be a decrease in the frequency of these complications as the problem receives further study.

The author cites the opinion of Kirwin (*Surg. Gyn. Obst.*, 1938, 66, 998) who suggested partial cystectomy with destruction of the tumor by electrocoagulation with or without radium implantation as the treatment of choice in bladder cancer. After his experience with 3 cases, the author concluded that this method was not a satisfactory one, "for how can one accomplish the destruction of the tumor by partial cystectomy or by electrocoagulation without exposing the patient to the great risk of recurrence?"

Some good results have been obtained with x-ray and radium therapy. However, radiation therapy is difficult to administer in the proper dosage. It tends to accentuate the cystitis and in itself is not without danger.

Contact radiotherapy too has produced some good results. Durget and Duvergey treated 3 patients with large bladder tumors by contact radiation in doses of from 8,000 to 16,000 roentgen units with good results, lasting from 6 to 13 months.

If similar results are published, one might be inclined to consider this method of treatment for all tumors of the bladder. Actually, however, it is difficult to evaluate this method because it is not easily administered. It may be the method to use when it is impossible to do a total cystectomy. The author reviewed the work of Higgins (*Surg. Gyn. Obst.*, 1938, 66, 549) on total cystectomy and transplantation of the ureters into the intestines for cancer of the bladder. Higgins concluded that total cystectomy with

intestinal transplantation of the ureters is advisable for cancer at the base of the bladder, large tumors, multiple tumors, recurrent tumors, and, in particular, for those patients whose general health is good and those whose urograms show favorable function of the upper urinary tract. These patients must be without pulmonary and lymphatic metastases, however.

On the basis of his own experience and a review of the literature Godard concludes that total cystectomy for vesical cancer can be performed if the ureters are not dilated, but if they are, the ureters can be transplanted into the skin, otherwise, they can be transplanted into the intestine. In J. P. Robert's technique (Paris, 1943), the bladder is opened, the lesion is examined, and, by extraperitoneal approach, the ureters are brought to the skin. The mortality from this procedure was 15 per cent with frequency survivals of 5 to 10 years.

If the patient does not wish to accept this disagreeable infirmity of ureterocutaneous implantation, the other alternative must be ureterointestinal anastomosis.

With improved surgical technique, the gravity of this operation, it is hoped, will be diminished and the operation will not have to be abandoned.

In spite of considerable extension the tumors are frequently surgically removable.

The author then reviews the operative technique of ureterointestinal anastomosis as described by Hinman, Brenizer, Jewett, and Flocks. He concludes that the numerous techniques of anastomosis justify further research and perfection of operative methods in order to lower the number of postoperative infections.

Godard describes his method of total cystectomy and ureterointestinal implantation. The operation is divided into two stages. The first operation consists of a right colostomy with the formation of an artificial anus. Under local anesthesia a right subhepatic colostomy is done. The posterior portions of the cecum are maintained in order to facilitate closure of the cecum at a later date. A glass tube is placed into the colostomy in order to permit lavage of the colon and also to provide an outlet for the fecal stream. This procedure then allows for frequent colonic lavages and diversion of the fecal stream prior to ureterointestinal anastomosis. Godard believes this procedure reduces the infectious complications of the operation.

In about 10 days the second stage of the operation is performed. This consists of ureterointestinal implantation. The technique is much the same as that of Coffey. He uses a metal guide or a mandrin that is fastened to the end of the ureteral catheter to facilitate the passage of the catheter through the mucosa of the bowel. The trocar at the end of the catheter is picked up by inserting a resectoscope into the rectum, then the catheter is pulled through the rectum until the proper adjustment has been made. The catheter is then fastened in a trough, as in the Coffey II technique, while the distal end of the

catheter is brought out through the rectum. The same procedure is carried out on the opposite ureter. The total cystectomy is performed according to the usual technique. In the female the author removes en bloc the uterus, top of the vagina, and the bladder. The colostomy is then closed 3 to 4 months later.

In summary, the author concludes that, in spite of the dangers of the operation that cannot be completely overcome by our technique, ureterointestinal anastomosis remains the treatment of choice for cancer of the bladder and vesical exstrophy. He proposes a preliminary operation to deviate the fecal stream which improves the immediate postoperative prognosis and to a certain extent avoids renal infection until cicatrization and sphincterization of the ureters can take place. In the choice between contact radiotherapy and total cystectomy, a great deal of clinical judgment is required, but with the increasing progress of physical therapy (contact therapy, beta therapy, and injectable radioactive substances), it is possible that operative techniques will form only a minor part of treatment of vesical cancer.

BLADDER, URETHRA, AND PENIS

An Attempt at Classification of the Tumors of the Bladder (Ensayo de clasificación de los tumores de vejiga) ARMANDO TRABUCCO *Rev. argent. urol.*, 1947, 16, 409

Tumors of the bladder may be divided basically into monoblastomas, or tumors which are thought to originate from one only of the germ layers of the embryo, and polyblastomas. The latter are rare, being made up almost exclusively of the teratomas (benign), or adult tissue polyblastomas, and dysembryomas (malignant), or poorly differentiated tissue polyblastomas.

The monoblastomas are in turn classifiable into epithelial tumors and connective tissue (conjunctival) tumors. Each of these two categories may be again subdivided into homotypical monoblastomas, or tumors whose tissues conserve the anatomical likeness and other kinship to the parent tissue of the bladder from which they originate, and the heterotypical monoblastomas which vary in characteristics from any of the normal bladder tissues.

The homotypical, epithelial monoblastomas are, of course, composed of the various types of pavement-celled and glandular types of epithelioma, both benign and malignant. Here under the pavement-celled tumors are the papillary and infiltrating carcinomas of the bladder, and under the glandular type are the adenomas and adenocarcinomas (mucoid, colloid). The heterotypical epitheliomas include the spinous celled epithelioma, the chorioepithelioma, the cylindroma, the alantoid or alantoid tissue epithelioma, and the endometrioma, both adenomatous and carcinomatous.

The homotypical, conjunctival monoblastomas are the histiocytic conjunctival monoblastomas, such

as the fibromas and the fibroplastic sarcomas, the muscular tissue conjunctival monoblastomas, such as the leiomyomas and the leiomyosarcomas, the vascular tissue conjunctival monoblastomas (angiomas, hyperplastic angiomas, angiosarcomas, hemorrhagic angiomas of Kaposi, endotheliomas, endothelial sarcomas, lymphomas, lymphosarcomas), and they are tentatively allowed to include the so-called neural (?) tumors (neuromas, gliomas, neurosarcomas)

The remaining tumors of the bladder are finally grouped into the class of heterotypical conjunctival monoblastomas. These are the melanosarcomas, the rhabdomyomas and rhabdomyosarcomas, the osteomas and chondromas, the lipomas and liposarcomas, and the myxomas and myxosarcomas.

The polyblastomas are, of course, an extremely complex class of neoplasms and no attempt is made to subclassify them.

JOHN W. BRENNAN, M.D.

The Diagnosis and Therapeutic Indications in Tumors of the Bladder (Diagnostico e indicaciones terapeuticas en los tumores de vejiga) ARMANDO TRABUCCO and CONSTANCE COMOTTO *Rev argent urol* 1947, 16 399

In discussing the clinical symptoms, and cystoscopic and roentgenologic findings of value in determining the type and degree of malignancy, and consequently the methods of therapeutic procedure to be instituted, the authors divide the findings to be evaluated into six general categories. The first is devoted to the palpation of the empty bladder, the second to the type of vesical hemorrhage, the third to the cystoscopic findings in the tumor and the peritumoral zones, the fourth to the curability (or otherwise) of the inflammatory processes when they are present concomitantly with the tumor, the fifth to the roentgenographic images discernible with cysto-roentgenography, and the sixth to the general condition of the patient.

Palpation will disclose any inflammatory processes and tumorous infiltrations of the bladder walls. The inflammatory processes are prone to manifest themselves as pericystic adhesions, and, if extensive and tough, suggest malignancy of the tumor process and inoperability. Induration of the bladder wall also suggests a malignant character of the new growth, but pliability and resilience of the wall suggest benignity and curability by endovesical means.

When the hematuria is inconstant, not occurring very frequently and being easily affected by treatment, the tumor is benign, when the bleeding begins suddenly and is capricious and intractable the neoplastic process is apt to be malignant.

When the cystoscope reveals an intracystic growth, be it pedunculated (benign) or sessile (malignant), which is surrounded by a normal appearing, non-inflamed, noncongested, mucosa, the entire process is apt to be benign. When the peritumoral reaction is marked it indicates that the growth is extremely malignant and no time can be lost with conservative measures. The entire inside of the bladder can be

seen with the cystoscope and a general inflammatory appearance will speak for malignancy. The exact extent of the new growth will be revealed by the cystoscope, and its unilocal or multilocal character suggests malignancy.

The frequency of urination during the day and night, which is not influenced by general measures, chemotherapy, or the local treatment of the bladder, as one would expect in simple bacterial inflammation, is a grave sign. The pollakiuria, painful micturition and stranguria may be produced either by the infiltration and irritation of the nerve centers of the bladder wall, or by a general infiltration of the whole or greater part of the wall, which renders the organ inflexible and of small capacity. These symptoms become especially pronounced when the growth invades the region of the bladder neck and trigone.

All roentgenographic procedures should be preceded by a simple roentgen exposure, without contrast medium, to reveal any foreign bodies or calcareous deposits. The filming with contrast methods includes, of course, descending pyelography, which in cases of bladder tumors is invaluable for determining the length of the intramural portion of the ureter and thus the amount of periureteral neoplastic infiltration, as well as the retrograde filling of the vessel through the cystoscope or catheter with contrast medium or gas. The normal bladder wall gives a very thin line on the roentgenogram and any thickening or irregularity of contour indicates both the malignant character and the extent of infiltration of the tumor. Of course, the unilocal or multilocal character can be seen on roentgenoscopy, the pedunculated masses will appear as central shadow defects, accompanied perhaps by a lighter band indicating the peduncle. Roentgenologic examination when used in conjunction with other methods will always help in the determination of the grade of operability and curability of the tumor.

The general condition of the patient is not discussed at length since it is usually good until the cancerous process is far advanced, when metastases or profuse hemorrhages lead to the cachexia typical of cancer, without the prospect of any cure whatever.

JOHN W. BRENNAN, M.D.

The Relation of Transitional Cell Buds, Golgi Apparatus, and Mitochondria to Carcinoma of the Bladder ALBERT E. BOTHE and DAVID S. CRISTOL. *Am J Roentg*, 1948, 60 535

These authors simplify the classification of bladder tumors into pedunculated and nonpedunculated (or flat) types. Tumors of the first type are papillary, tumors of the second type are infiltrating. The small papillary growth, pedunculated and low grade, is best treated by transurethral fulguration followed by periodic cystoscopic re-examination. Up to the present time transurethral fulguration with insertion of one radon seed at the site of the pedicle has not been evaluated, the results of irradiating the recurrent growths from previously fulgurated tumors in this group also remain to be evaluated. In cases in

which multiple papillary growths of relatively low grade are found, extensive fulguration down to the muscle through a cystostomy, followed by radon seed implantation, seems to be the best method of management. Frequent re-examinations of the bladder should be performed. In cases in which flat infiltrating tumors are present, the extent of the infiltration should be determined by means of pneumocystography and bimanual examination of the bladder under anesthesia. The results of segmental and total cystectomy remain to be evaluated.

The authors studied the distribution and arrangement of transitional cells, and a cytological study was made of the Golgi apparatus and mitochondria found in malignant and nonmalignant cells of the bladder mucosa. The submucosal epithelial buds in the transitional cell-covered tissues of the bladder, described by von Brunn in 1893, appear to be susceptible to growth activity. The early changes in bladder tumors which first involve the submucosal epithelial supporting tissue are inflammatory in type. These changes are followed by proliferation of the basal layer which eventually becomes papillary or infiltrating. The anatomical distribution of these cell nests may be closely associated with bladder tumors, the multiplicity of the epithelial buds in the renal pelvis, ureters, and bladder is in accord with, and very suggestive of, the source of subsequently developing tumors, and the latter probably develop from these epithelial cell nests. If this (unproved) hypothesis is true, how may these immature imperfectly differentiated cell nests be rendered inactive or unsuitable to growth? On the basis of 5 case histories, the authors believe that roentgen therapy may change these epithelial cells so that the tissue is less susceptible to carcinogenic irritation.

In vesical epithelial cells the Golgi apparatus usually lies in the cytoplasm distal to the nucleus (between the nucleus and free surface). In 15 specimens of bladder tumor there was a reversal of the Golgi apparatus, they were present away from the nucleus membrane and were increased in size. In some, the mitochondria showed an increase in number and a decrease in size, in others, the reverse was true.

The authors conclude that if the tissues susceptible to activation by carcinogenic agents are the immature buds, irradiation of the urinary tract postoperatively (areas covered by transitional epithelium) may arrest or prevent the activation of cell buds.

DAVID ROSENBLUM, M D

Our Initiation into the Field of Total Cystectomy
(Nuestra iniciación con la cistectomía total) FRANK
A HUGHES *Rev argent urol*, 1947, 16 345

Six patients were cystectomized by the author in Montevideo, Uruguay, during the past year. The operation was attempted for infiltrating malignant tumor located in the neck and trigone of the urinary bladder. Three of the patients died within a short period following the operation—2 from complications ascribable to the operation itself, and 1 from extension of the neoplastic condition. Three are still liv-

ing, 2 of these after a year and 1 after only a few months following the operation but in excellent general condition. The operation was attempted in each case for the alleviation of suffering and for intractable bleeding. However, the intention in each case was the total removal of the neoplastic mass.

The actual removal of the bladder and prostate gland has proved less troublesome than the preliminary implantation of the ureters into the sigmoid. In the first patient the attempt at ureterosigmoidostomy failed and the implantation of the ureter was made into the skin. A second attempt by the technique of Jewett (*J Urol*, Balt, 1939, 49 34) also failed and resulted in the loss of the patient. In the subsequent cases this method of implantation was abandoned in favor of the classical technique of Coffey I. This technique was carried out extraperitoneally in 3 cases and intraperitoneally in 2. The implantation of the left ureter was carried out through the left paracolic space in 2 instances with failure of drainage of this ureter and loss of the left kidney function in each case. In subsequent patients the implantation of the left ureter was accomplished into the medial aspect of the sigmoid intraperitoneally by passing the ureter through the mesosigmoid. The 1 living patient in whom this technique was used showed no noticeable loss of renal function.

The ultimate fate of these living patients is, of course, problematical, however, the operation is believed to be a logical one since the great suffering and disability of the patient is largely relieved and the cancers of the urinary bladder are, on the whole, slow to generalize. Metastases are very rare as long as the tumor has not penetrated the muscular layer of the organ.

JOHN W BRENNAN, M D

GENITAL ORGANS

Blood Loss in Open Prostatic Surgery ALBERT E
GOLDSTEIN and SEYMOUR W RUBIN *J Urol*, Balt,
1948, 60 743

The authors have utilized the technique of photoelectric measurement of hemoglobin to determine the blood loss in the operating room in a series of 48 consecutive open prostatectomies. The entire operating room equipment which had contacted blood was washed in a solution of 0.4 per cent ammonium hydroxide of measured amount, the solution thoroughly mixed, the concentration of hemoglobin determined, and this figure corrected for the patient's own preoperative blood hemoglobin concentration, so that the result would be expressed in terms of cubic centimeters of blood lost.

In 16 cases of two-stage suprapubic prostatectomy performed, the smallest blood loss in the first stage was 3 c.c., the largest 102 c.c., and the average 34 c.c. In the second stage, the smallest loss was 19 c.c., the largest 569 c.c., and the average 157 c.c. The combined average was thus 191 c.c.

The smallest amount of blood loss during 5 one-stage suprapubic operations was 137 c.c., the largest 381 c.c., and the average 278 c.c.

Perineal prostatectomy was performed in 27 cases with radical removal in 4. The smallest blood loss in the conservative group was 128 c.c. the largest 1307 c.c., and the average 403 c.c. The average loss in the 4 radical cases was 1,131 c.c. The blood loss in 8 cases of retropubic prostatectomy averaged 403 c.c.

The authors present the view that although more blood was lost in the perineal procedures, the patients were less shocked than the patients who lost less blood during suprapubic procedures. The authors believe that the position of the patient, length of time of operation, handling of the tissues, and balance of the body fluids all play a part in the production of shock.

JOSEPH E. MAURER, M.D.

Testicular Tumors Seminoma and Teratoma

ROBERT E. SCULLY and ASA R. PARHAM *Arch Path., Chic., 1948, 45: 581*

The author's study is based on a review of 37 cases of testicular tumors from the files of the department of pathology of the Peter Bent Brigham Hospital, for the period from 1914 to 1947.

Tumors of the testicle comprise 2 per cent of all cancers in males. They occur at any age, usually between the ages of 20 and 30 years. Approximately one of every 8 of these tumors is located in a cryptorchid testicle. Rarely a testicular tumor is bilateral. A history of trauma had been reported in from 20 to 68 per cent of cases, but most authors have minimized its significance as an etiological factor.

Testicular tumors metastasize primarily by way of the lymphatic channels. These, for the greater part, drain directly into the abdomino-aortic nodes, which extend from the bifurcation of the aorta to the level of the renal veins. There is widespread anastomosis between both sides. The abdomino-aortic nodes drain into the lumbar tracts, which ascend through the aortic hiatus of the diaphragm to the thoracic duct. There may be one or more channels from the testis that drain directly into the mediastinal nodes. Enlargement of the inguinal nodes indicates invasion of the parietal tunic and the scrotum. Blood stream metastasis likewise is common and occurs most frequently in the lungs, but may be widespread.

Patients with testicular tumors usually excrete measurable quantities of gonadotropins in the urine. Two distinct types have been identified: the first type of gonadotropin is biologically similar to the pituitary gonadotropin and the second type is biologically identical with the chorionic gonadotropin of pregnancy. In a certain number of cases the titer of chorionic gonadotropin is sufficiently high to justify an Aschheim Zondek or Friedman test of the conventional type for pregnancy.

In general the classification of testicular tumors has been based on one of two theories of pathogenesis, neither of which has been supported by convincing evidence. It is stated that (1) all the common testicular tumors are forms of teratoma and (2) the histologically uniform neoplasms represent the undifferentiated development of teratoma. The authors con-

cluded that this histologically uniform tumor which he named "seminoma" because of its supposed origin from the seminiferous tubules, is a distinct tumor not arising from a teratoma.

The authors have retained the term "seminoma" because of its universal use for the common histologically uniform monocellular neoplasm. The term "teratoma" is used to designate a tumor arising from a cell which has the capacity to form structures normally derived from the three embryonic germ layers. There are two subtypes: one is characterized by the presence of neoplastic structures representing two or more germ layers, the other (the monodermal variety) is characterized by a type of tumor tissue foreign to the testis, the presence of which is best explained by regarding it as a one-sided neoplasm of a cell with totipotential capacities.

1. Seminoma (embryonal carcinoma)
2. Teratoma (embryoma)
 - (a) Histologically cancerous
 - (b) Histologically benign (adult teratoma)
3. Interstitial cell tumor
4. Miscellaneous group

The results of the conventional Aschheim Zondek and Friedman tests are usually negative in cases of seminoma. The seminomas constituted 46 per cent of testicular tumors. Testicular enlargement was the presenting symptom in 12 of 14 cases of seminoma. The incidence of metastases in case of seminoma is controversial. In the authors' series 4 of 14 patients had metastases at or within one month after entry to the hospital; in the remaining 10 patients, the tumor metastasized subsequently. Usually involvement of the abdominal or cervical lymph nodes gave the first indication of tumor spread; terminally, widespread blood borne metastases were common. The histological structure of the metastases in all cases examined was identical to that of the primary tumor.

The striking x-ray sensitivity of seminoma has been noted by numerous authors. Scully and Parham indicated that the good prognosis of seminoma in their cases was in accord with the experience of numerous other investigators.

The typical specimen of histologically cancerous teratoma is a circumscribed, firm mass which has enlarged and replaced all or the greater part of the testicle. Microscopically, the tumor is composed of an intimate mixture of teratomatous and cancerous neoplastic tissue.

Testicular teratoma may arise from (1) totipotent sex cells or their embryonic products or undifferentiated type of neoplasia due to parthenogenesis, or (2) intratesticular inclusions of totipotent primitive embryonic cells (blastomeres). The former variety is far more likely in view of the prebudding of teratoma for the sex gland and the distinctive features of teratoma in this location compared with extra-genital teratoma.

Histologically, cancerous teratoma is characterized by the presence of the histological features of carcinoma and teratoma. The tumor contains a variety of

amounts of trophoblastic neoplastic tissue giving the highest titers. Histologically, cancerous teratomas constituted 43 per cent of tumors in this series.

Numerous authors have observed that these tumors tend to metastasize rapidly and that early blood stream dissemination is frequent. This impression was borne out in the authors' series. The radioresistance of cancerous teratoma has been noted by numerous authors and this was again borne out by the authors' series of cases.

Histologically, benign teratoma may fall into one of three ill defined subtypes (1) organized teratoma, (2) unorganized teratoma, (3) simplified teratoma. An organized teratoma is a rare complex tumor in which rudimentary organs are formed and may be so arranged as to resemble a malformed fetus. In the unorganized teratoma neoplastic structures of bidermal or tridermal origin appear in disorderly arrangement in an attempt at organ formation. Simplified teratoma is the monodermal form. Its most common variety is the epidermoid cyst, and less frequently encountered is the dermoid cyst. Often it is found that histologically benign teratomas have metastasized. The secondary deposits may show histologic structure of cancerous teratoma or embryonal adenocarcinoma. Quantitative studies in a small series of cases have revealed little or no increase in excretion of gonadotropins in the urine of patients who have these tumors. The metastases of histologically benign teratoma have been stated to be radioresistant.

In summary, the author states that over 95 per cent of testicular neoplasms fall into two classes: seminoma and teratoma. The seminoma apparently arises from a primordial germ cell. Its histological uniformity is due to the inert characteristic of its cell which appears incapable of differentiation. The tumor usually grows relatively slowly, metastasizes late, and principally by the lymphatic route. It is highly radiosensitive and occasionally radiocurative. The testicular teratoma apparently arises from the totipotent sex cell or from one of the embryonic predecessors of this cell. Histologically, it may run the gamut from a highly undifferentiated embryonal neoplasm to a mature teratoma showing no microscopic evidence of cancer. The tumor characteristically grows rapidly and metastasizes early, commonly by way of the blood stream. It is rarely radiosensitive, and almost never radiocurative. Occasionally seminoma and teratoma grow side by side, and occasionally they may become intimately mixed. The article contains many excellent illustrations of the types of tumor described by the authors.

CONRAD A. KUEHN, M.D.

MISCELLANEOUS

Renal Response to Thermal Stimulus L. D. ODELL, G. T. ARACON and R. C. SMITTER. *Am J Obst*, 1948, 56: 835.

The authors report their findings of renal activity following a 15 minute immersion of one hand or a

foot in an ice water bath at a temperature of one degree centigrade. This test was carried out on 33 women—22 with toxemia of pregnancy, 1 woman with a glioma of the spinal cord during pregnancy, 1 with diabetes insipidus during pregnancy, and 9 nonpregnant women.

The results show a decreased flow of urine, an increase in the specific gravity of urine and, in some instances, a change in protein excretion per minute. Variations in systolic and diastolic blood pressure accompany this experience but do not correlate, in the degree of the response, with the protein excretion per minute.

The fetal heart rate does not vary significantly. Maternal pulse and respiratory rates tend to decrease.

Experiments conducted under anesthesia indicate that ice immersion may stimulate the liberation of an antidiuretic hormone. The site of liberation is probably not within the immersed limb or the kidney, it appears to be above the level of the fourth cervical. The phenomenon is not abolished by inhalation anesthesia. The site of liberation may be the posterior pituitary gland.

JOHN R. WOLFF, M.D.

Neuromuscular Dysfunction of the Urinary Tract

JAMES C. KIMBROUGH, DAVID K. WORGAN, and JOHN N. FURST. *J Urol*, Balt., 1948, 60: 780.

The authors present 6 cases of neurogenic dysfunction of the urinary tract. All of the patients had atony of the bladder and ureters with hydronephrosis, all patients complained of abdominal symptoms prior to urological investigation, a diminished renal function, varying from moderate to extreme, was observed in all cases. In none of these patients was a sensory or motor impairment found upon general neurological examination, and none demonstrated idiopathic dilatation of the intestine.

The treatment administered by the authors in the cases presented included ureteral meatotomy, transurethral resection of the vesical neck, presacral neurectomy, and renal sympathectomy. Measures to control infection in the urinary tract were instituted.

The need for careful follow-up therapy in all cases of neurogenic dysfunction of the urinary tract is stressed. The opinion is mentioned that hydronephrosis without tortuosity of the ureters is suggestive of neurogenic disease.

JOSEPH E. MAURER, M.D.

Urinary Tuberculosis REED M. NESBIT and A. WAITE. *BOHNE J Am M Ass*, 1948, 138: 937.

The authors contend that all patients with either unilateral or bilateral renal tuberculosis should receive prolonged sanatorium care and streptomycin therapy.

This contention is supported by the following pertinent facts:

1. A patient in whom ulcerative lesions eventually healed on this regimen is cited in refuting the claim of other authors that only very early renal tuberculosis can be cured with streptomycin.

2 Reference is made to the exhaustive pathologic studies by Medlar who examined serial sections of the kidneys from individuals who died of pulmonary tuberculosis and found that bilateral cortical infections were present in all the kidneys

3 Combined statistics from the Squier Clinic, New York, the Mayo Clinic, Rochester, Minnesota, and the University Hospital, Ann Arbor, Michigan, reveal that only about half of the patients can be cured by nephrectomy, even when the operation is done under ideal circumstances

The use of very small doses of streptomycin for short periods with the hope of avoiding toxicity is condemned. Although optimal dosage and duration remain uncertain, the authors recommend 20 gm of streptomycin daily for 60 days. At the end of this time, complete studies of the urine and retrograde pyelograms should be made. If these show evidence of healing, the treatment should be continued for an additional 60 days. If the 60 day survey reveals no improvement, nephrectomy is justified but should be followed by 60 days of streptomycin therapy. All patients should have a minimum of 6 months of sanatorium care

ORMOND S. CULP, M.D.

Tumor and Superimposed Cyst of the Urachus (Tumor y quiste supurado del uraco) JOSÉ S. DORTA *Rev argent urol*, 1948, 17: 174

The case reported by the author was that of a 59 year old male who complained of a indurated area in the midabdominal line from the umbilicus to the symphysis pubis. There was dense subcutaneous fat underlining the region which was very tender and which made palpation difficult. Cystoscopy revealed an infiltrating tumor in the dome of the bladder. This suggested the diagnosis of urachal cyst superimposed upon a vesical tumor.

Operation was performed and both masses were removed *in toto*, including resection of the umbilicus and the dome of the bladder. Convalescence was uneventful and was followed by deep roentgentherapy. The tumor was of an intramural type and has shown no evidence of recurrence either in the abdominal portion or in the bladder.

STEPHEN A. ZIEMAN, M.D.

Cancer of the Urachus (Cancer del uraco) RICARDO ERCOLE *Rev argent urol*, 1948, 17: 193

Cancer of the urachus is a rare disorder. There are apparently only 164 cases of this condition on record. It is a disease of adult life and usually involves the dome of the bladder. For this reason therapy involves bladder surgery.

The case reported is that of a 64 year old male who complained of pain in the hypogastrium, burning on urination, and polyuria. Only on cystoscopic examination was the presence of a tumor observed. This was a sessile, ulcerated fungoid mass in the dome of the bladder, a section of which was removed for biopsy. The pathologic report returned gave a diagnosis of cylindrical papillary epithelioma with origin in the epithelial rests of the urachus.

The author calls attention to the fact that tumors in the upper regions of the bladder may well be of urachal origin and must be differentiated from primitive adenocarcinoma of the bladder. The latter, it is stated, arise from the bladder mucosa and secondarily invade the muscle layer, whereas urachal tumors invade the muscular layer primarily and the mucosa only secondarily. Treatment consists in resection of the tumor, which may include the dome of the bladder or even complete cystectomy and removal of all umbilical tissue if the extension of the growth demands it.

STEPHEN A. ZIEMAN, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

**Legg-Perthes' Disease A Syndrome of Many
Etiologies?** S Z DRAZNIN and KARL SINGER.
Am J Roentg, 1948, 60 490

This disease was first described by Legg and independently by Waldenstrom in 1909, and in 1910 by Calve and Perthes. The latter gave a more clear-cut description of the clinical picture and the roentgenographic findings. Among the names given to the disease are osteochondritis deformans juvenilis, pseudocoaxalgia, quiet disease of the hip, osteochondrosis, and coxa plana. Gill has expressed the belief that the primary location of the disease is in the metaphysis of the neck rather than in the capital epiphysis.

Among the etiological theories advanced are the following: traumatic, infectious, congenital stigmata, unrecognized congenital dislocation, rickets, rheumatic, endocrine, embolic, vascular, familial osteochondritis, similar to Koehler's disease, and alterations in the calcium-phosphorus metabolism. Gill states that it is doubtful that all types of osteochondritis deformans juvenilis are manifestations of the same pathologic process. The condition is often mistaken for acute osteomyelitis or tuberculosis of the hip joint.

The authors have added Gaucher's disease to the list of etiologic factors. They present a case of proved Gaucher's disease which had been followed up for 18 years. The patient presented the roentgenographic features of Legg-Perthes' disease.

DANIEL H. LEVINTEAL, M D

**Diffuse Inflammation of Cartilage A Case Report
of a Hitherto Unreported Entity** EVERETT J
GORDON, AARON W. PERLMAN, and NATHAN
SHECHTER. *J Bone Surg*, 1948, 30-A 944

This comprehensive report of a case of diffuse inflammation of cartilage observed over a period of 3 years is considered most unusual in that no diagnosis has been made in spite of extensive pathologic studies.

A 34 year old negress first complained of a productive cough and dyspnea. Roentgenograms of the chest showed no evidence of tuberculosis. After several months, swelling and tenderness of the knee and ankles was observed, with remissions and exacerbations, sometimes febrile. Swelling of an eye and both ears, and increasing cough and hoarseness ensued. Hospitalization failed to yield a definite diagnosis, although exhaustive studies were carried out. Fluid aspirated from the involved knee joint did not yield organisms, and sulfamerazine therapy did not influence the clinical picture. Tracheotomy was necessary in patients with severe obstruction due to chondritis of the tracheal rings.

A 2-plus Kahn test led to antisyphilitic therapy of potassium iodide and bismuth in oil. A total of 1,320,000 units of penicillin was administered. On x-ray examination the left knee and both ankle joint spaces showed narrowing. Episodes of iritis and conjunctivitis recurred repeatedly. There was persistent tender swelling of both ears and of the bridge of the nose. Remissions and exacerbations continued in the various affected areas.

Because of extreme pain from the slight motion residual in the left knee, arthrodesis was undertaken, following which the patient failed to respond. Autopsy was not secured.

Careful studies of cartilage taken from the various sites affected have been made by several pathologists. Nothing more conclusive than "diffuse chondritis and perichondritis" has been determined.

FRANCES E. BRENNKECKE, M D

**Tenosynovitis of the Extensor Carpi Ulnaris Tendon
Sheath** DOUGLAS D. DICKSON and CLARENCE A.
LUCKEY. *J Bone Surg*, 1948, 30-A 903

Nonsuppurative tenosynovitis of various tendon sheaths of the hand, frequently the extensor pollicis brevis or abductor pollicis longus, is described. Tenosynovitis of the extensor carpi ulnaris tendon sheath is here presented as a clinical entity proved by surgery in 6 cases.

The history usually dates from a twisting injury to the wrist, followed by pain deep in the wrist joint, which may be aggravated by all wrist motions. There may be swelling about the distal ulna and sensory disturbance along the dorsal cutaneous branch of the ulnar nerve. Examination shows tenderness along the tendon and may elicit grating in the sheath with motion. Resisted motion defines the pain more readily.

Pain which persisted or remained in spite of varying periods of wrist immobilization led to surgical exploration of the 6 cases presented. Edema of the subcutaneous tissues surrounding the dorsal branch of the ulnar nerve was a constant finding. The dorsal carpal ligament was sectioned to show the extensor carpi ulnaris tendon sheath within which the synovia was thickened, and many new vessels were present. The tenosynovitis was most marked in the snug portions of the sheath, i.e., the channel on the ulna, and at the insertion.

Probably hemorrhage within the tendon sheath produces the nonspecific inflammatory reaction in the synovia.

The diagnosis of tenosynovitis should be suspected when the patient complains of pain deep in the wrist. Opening of the fibrous tunnel throughout its length would probably relieve the symptoms, although in these cases the thickened synovia and granulations were removed in addition.

FRANCES E. BRENNKECKE, M D

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

The Treatment of Compound Injuries of the Knee Joint (Zur Behandlung offener Kniegelenksverletzungen) JOHANNES VOLKMANN *Chirurg*, 1948, 19 343

In cases of compound injuries of the knee joint in which x-ray facilities are unavailable the joint is left open. The knee is splinted, aspirated, and irrigated with a sulfonamide compound. The joint may stay open up to 36 hours without any harmful effects.

As soon as a well equipped operating room is available a tourniquet is applied to the leg under general anesthesia and an incision is made similar to the one used in meniscectomy. The wound is debrided with 1 to 1,000 ravinol. The synovia is closed tightly with catgut and the capsule is united with cotton sutures. The skin may be left open or is loosely sutured. No drain is used. A long leg cast is then applied. Sulfanilamide is given by mouth. Mobilization of the leg is begun as soon as the condition improves. First the foot is left free and then the hip, and finally the cast is removed entirely.

In cases in which conservative treatment fails, 4 wide incisions are made over the knee joint. Once the infection has subsided, closure of the wound is attempted.

FRACTURES AND DISLOCATIONS

Intracapsular Fractures of the Neck of the Femur Follow-Up Report of 130 Patients Treated by Internal Fixation with the Smith-Petersen Nail. CHARLES S. NEER and HARRISON L. McLAUGHLIN *Am J Surg*, 1948, 76 528

The authors review 130 consecutive intracapsular hip fractures treated on the Fracture Service of the Presbyterian Hospital, New York, between 1932 and 1944. True intracapsular lesions occurred in approximately 50 per cent of all hip fractures. A Smith-Petersen nail was used in each case. Fractures of more than 2 weeks' duration were excluded.

Every hip fracture was considered an acute emergency. Operation was usually performed within 1 or 2 hours, and in 80 per cent of the cases within 6 hours of admission. Impacted valgus lesions were nailed without reduction or visualization of the fracture. All displaced fractures were reduced prior to fixation. In 73 cases this was done under direct vision and in 31 cases under roentgenographic control. Subcapital oblique fractures proved to be the most difficult to reduce and frequently could not be reduced adequately by manipulation alone. The authors have developed a policy of modifying the lesion so that the line of fracture approaches the horizontal plane. Following operation, 65 per cent of all the patients were allowed out of bed within 24 hours. Those physically able to use crutches began to walk without weight-bearing in a walker about the fourth postoperative day and were promoted to crutches as rapidly as they could tolerate them.

The authors believe that the morbidity constantly diminished in direct proportion to the speed and efficiency with which stabilization of the fracture was carried out. The mortality was divided into three categories: (1) operative mortality, including deaths from any cause during the first 30 days following operation (there were 2 deaths in this group, 1 from a pulmonary embolism 28 days after operation, and 1 from cardiac failure 4 days after operation); (2) mortality related to injury, including deaths related to the injury occurring within 9 months of operation, (there were 2 deaths in this group, 1 at 4 months, from pulmonary embolism, and 1 at 7 months, due to infection of the hip and pneumonia); (3) mortality unrelated to injury, including all deaths from unrelated causes between the end of the first month and the ninth month (there were 8 in this group: 3 cardiac infarctions, 2 cerebral accidents, 1 malignancy, 1 renal failure, and 1 suicide).

There were 26 cases of impacted valgus fractures. There were no deaths or wound infections in this group. The average hospital stay was 14 days, and the average weight-bearing time 5 months. Twenty-three cases (92%) were followed up adequately, and among these there were no nonunions, 3 cases of mild necrosis, and 1 case of severe necrosis. "Mild" necrosis indicates avascular changes affecting only the roentgen texture of the femoral head. "Severe" necrosis indicates changes pronounced enough to change the shape or contour of the femoral head. The term "arthritic change" tends to confuse the issue and is omitted.

There were 104 cases of displaced fractures. The operative mortality was 1.3 per cent in 73 cases treated by open reduction and 3.2 per cent in 31 cases treated by closed reduction and lateral nailing. Closed reduction and lateral nailing constantly required more time than open reduction and nailing under direct vision. It was also a constant observation that (1) regardless of the characteristics of the fracture, reduction and fixation were accomplished more certainly and accurately when carried out under direct vision, and (2) this unselected group of patients withstood the effects of open reduction as well as, if not better than, manipulative reduction and blind nailing.

The early complications of 73 displaced fractures treated by operation were: poor reduction (15%), serious infection (1 case), trivial infection (8%), and loss of fixation (15%). The early complications of 31 cases treated by closed reduction and lateral nailing were: poor reduction (45%), trivial infection (10%), and loss of fixation (7%).

There were 21 cases of nonunion in 101 displaced fractures (72% of all the nonunions were in the subcapital fractures). Among 73 displaced fractures treated by open reduction, there were 16 cases of nonunion. Eleven were attributed to poor reduction, 2 to poor fixation, 2 to too early ambulation with weight-bearing, and 1 case to failure of the local circulation. Among 31 displaced fractures treated by closed reduction and lateral nailing, there were 5

cases of nonunion Four were considered to be due to poor reduction and 1 was due to poor fixation

In determining the number of cases of avascular necrosis, 18 months were considered to be the minimum adequate follow-up period Thus, only 74 of the 104 displaced fractures were considered Forty-two per cent of the healed fractures treated by open reduction and 54 per cent of those treated by closed reduction and lateral nailing subsequently developed aseptic necrosis Eleven months was the average interval between operation and demonstrable early avascular changes In spite of the much higher proportion of subcapital fractures in the open reduction group, the incidence of aseptic necrosis remained consistently less than in the simpler cases treated by closed reduction This finding contradicts the widespread impression that open reduction contributes to avascular necrosis

In 18 cases observed between 1933 and 1937 a flap of rectus femoris or vastus lateralis muscle was inserted into a decorticated area on the anterior surface of the head and neck of the femur in the hope that it would increase the local blood supply to the head fragment The results of analysis of 13 suitable cases warrant little optimism that the procedure was of any help in preventing aseptic necrosis or of any aid in the healing of the fracture

The authors consider these results discouraging and humbling Almost every poor surgical result was found to be due to some controllable defect in the technique of therapy Although the patient was satisfied in 86 per cent of the cases treated by open reduction and 92 per cent of those treated by closed reduction and lateral nailing, the surgeon was satisfied in only 25 per cent of the former and 20 per cent of the latter

The authors arrive at the following conclusions

- 1 The best time for reduction and fixation of a hip fracture is immediately after the fracture
- 2 Good treatment for impacted valgus fractures of the femoral neck is internal fixation and as little confinement to the bed as possible
- 3 Open reduction, properly done, is surer, less time consuming, and no more dangerous than closed reduction and blind nailing
- 4 Open reduction does not increase the incidence of subsequent aseptic necrosis
- 5 Results are known only after objective evaluation
- 6 Almost all the bad results of hip nailing are still the results of bad hip nailing

JOHN J. CRANLEY, JR., M.D.

General Conceptions of Pseudarthrosis Statistical Considerations (Concepto general de pseudarthrosis Consideraciones estadísticas) OSCAR R. MARÓTTOLI *An Ciruj*, Rosario, 1948, 13 23

During the period from 1943 to 1946, at the public hospital in Rosario, where the injured are brought directly for immediate treatment, 7,654 fractures were supervised continuously during the entire period of healing Only 0.1 per cent of this number

presented pseudarthrosis In the author's private practice, on the other hand, the pseudarthroses were much more numerous They occurred mostly in patients who had been originally treated on other services In the author's material the fractures most prone to develop pseudarthrosis were those of the neck of the femur and of the carpal scaphoid bone

True pseudarthroses may be roughly classified into (1) those which do not consolidate because of the absorptive processes in the ends of the bony fragments (the author ascribes these to the excessive congestion and dilatation of the blood vascular system and states that these pseudarthroses will heal without further trouble, as a rule, when properly immobilized), and (2) the fractures which fail to consolidate because of poor blood supply These pseudarthroses will not heal, as a rule, because of the eburnation and occlusion of the marrow cavity of the fragments, and the line of fracture and the bone ends will have to be removed surgically

The author concludes, from his own experience and from a study of the literature, that the fractures most resistant to the processes of consolidation are those which are most difficult to immobilize properly, and that the development of the pseudarthrosis is largely a result of improper treatment methods Certainly there is nothing about fractures of the neck of the femur and of the carpal scaphoid bone which suggests that they would not heal as readily as other fractures if they could be sufficiently retained during the period of consolidation

The Experiences and Results of Various Operations for Habitual Dislocation of the Shoulder (Erfahrungen und Erfolge bei den verschiedenen Operationsmethoden der habituellen Schulterluxation) OSWALD ADAM. *Chirurg*, 1948, 19 368

This article is based on 23 operations Ten shoulders were operated on according to the Eden-Hybenette method, which consists of an insertion of a tibial graft anterior to the humeral head Nine shoulders were operated on according to the Loeffler-Joseph method (modified Nicola) and 3 according to the technique described by Heymanovitch which is very similar to the Nicola operation There was only 1 case in which only the capsule was tightened The author concluded that the Eden-Hybenette method of repair gives the best results

GEORGE I. REISS, M.D.

ORTHOPEDICS IN GENERAL

Estrogens and Bone Formation in the Human Female MARY S. SHERMAN. *J. Bone Surg.*, 1948, 30-A 915

A review of the literature on the relation between blood calcium levels and ovulation in birds and small mammals introduces an interesting case study. Interrelation of estrogens and bone growth in human females is known to exist but its mechanism is not understood Postmenopausal osteoporosis has been

established clinically by Albright as a hormonal deficiency influenced by the injection of estrogens, without demonstrable increase in bone density. A spectacular variation in bone density during the administration of estrogens is demonstrated.

The woman was perfectly well until the age of 54, when the right tibia began to bow. Soon thereafter, while jumping rope (!), the left knee was injured. Roentgenograms were interpreted as showing Paget's disease but no fracture. Later in the same year the patient suffered a fracture of the lower right femur with moderate trauma, and she became bedridden because of the fracture and increasing bone pain. Deafness began to develop. Subsequent roentgenograms showed changes in the skull, pelvis, femurs, right tibia, and right humerus. The condition was diagnosed as parathyroidism and two parathyroid glands were removed, but the patient's condition continued unchanged.

During the next 2 years she was bedridden with agonizing bone pain, multiple fractures, cramps, and muscle twitching. At the age of 58 years she was admitted to the University of Chicago Clinics. Anesthesia was needed to control pain so that roentgenograms could be taken. Clinically, the right leg seemed boneless, and roentgenograms scarcely demonstrated the tibia, while the extremely osteoporotic femur presented multiple fractures.

Extensive studies, particularly on calcium excretion, were carried out and a biopsy of affected bones was secured. Beyond a marked decrease of bone substance, these specimens were not remarkable. On the basis of the data assembled, i.e., normal blood calcium and phosphorus, low urine calcium, and a normal histological picture, a diagnosis of Paget's disease with superimposed postmenopausal osteoporosis was entertained. (The patient had a surgical menopause 17 years earlier.)

Massive doses of estrogenic hormone gave a rapid change of clinical picture in 3 days, and after a month the patient sat in a chair for meals. Roentgenograms at one month showed well defined bones in the right leg with abundant callus healing of the fractures in the femur. Biopsy specimens affirmed this reconstitution of bone. Withdrawal of estrogen therapy promptly produced an exacerbation of symptoms which receded on resuming the estrogen therapy. A maintenance dose was worked out, and the patient has been kept on that for a period of 2 years, with no untoward symptoms.

FRANCES E. BRENNKE, M.D.

A Study of the Longitudinal Arch of the Foot A. K. BASU *Ind J Surg*, 1948, 10: 255

The influence of postural tone on the longitudinal arch of the foot is not clear. Postural tone is a state of continuous contraction of certain skeletal muscles which maintain the position of posture. This tone is a system of reflexes, whose afferent impulses originate in the sense organs of a group of muscles, aided by the eyes and vestibular apparatus. Exact anatomic localization of the center is equivocal, but it

may be found in the red nucleus and in the rubro-spinal tract.

Collapse of a longitudinal arch is predicated upon the superimposed dead weight and/or long periods of standing on the foot. Nurses, policemen, and waitresses rate highest in pes planus. In contradistinction, people who walk for long distances, with or without shoes and enjoy rest between long hikes develop less static disturbances of his feet. Hence, the hypothesis of muscle indefatigability in the maintenance of a suitable arch is not tenable.

The author undertook to study the behavior of the longitudinal arch under (1) spinal anesthesia, (2) complete paralysis of the lower extremities, (3) extensive inflammatory conditions about leg and foot, (4) acute toxemic conditions, (5) late stages of pregnancy, and (6) footprints obtained from recently amputated legs.

Spinal anesthesia studies were carried out on 15 patients who underwent various surgical operations under spinal anesthesia and revealed negligible longitudinal arch changes.

Twenty cases of paralysis of the lower extremities were studied. The paralysis, for the most part, was due to trauma. In 2 cases it was due to transverse syphilitic myelitis and cerebral thrombosis, respectively. According to the postural theory, abolition or relative diminution of the arch would be envisaged, but the observation failed to show any appreciable change in the integrity of the arch.

Nineteen cases of acute inflammatory lesions of the leg and foot were included in this series. The inflammations were ascribable to cellulitis, osteomyelitis, and compound infected fractures of the foot. Again, according to the postural theory, i.e., inhibition of the postural tone of the inflamed muscles, falling of the arches was not evident. When the inflammatory agency included the ligamentous capsular apparatus, however, the arch did collapse rapidly.

Twenty-eight cases of an acute toxemic condition were observed, the patients were suffering from pneumonia and enteric fever. It is alleged that the tone of the musculature, under toxemic states, was markedly reduced. In none of these patients, nor in others chronically ill with emaciating diseases, did collapse of the longitudinal arches ensue.

The footprints of 30 pregnant women were studied either before or after delivery. Since flaccidity and generalized ligamentous relaxation is emblematic of pregnancy, it may be expected that pes planus is a concomitant of pregnancy. The average arch fraction was 45.

Seventy-two pounds of pressure were exerted on each of 19 feet on recently amputated legs. If the arch was solely maintained by the postural tone of the muscle, lowering of the arch would be expected. This did not occur.

Several feet were prepared and comparable weights (36-72 lbs.) were arranged to exert perpendicular pressure on the longitudinal arch to determine the influence of ligamentous support on the

arch of the foot One foot had all of its ligaments intact, whereas, its fellow had its ligaments cut In the latter, the same weight caused collapse of the arch, and in the former the arch maintained its relative position

Stages in the development of the arch of the foot after birth were studied About 200 extremities of babies from birth to the age of 10 years were observed Immediately after birth, and up to the age of 5 months, the arch was not demonstrable The toes were divergent, the heel was small, flexion creases were prominent, and the foot assumed a triangular characteristic similar to prints obtained in a matured monkey It was not until after 18 months that the arch made its appearance Between the ages of 2 and 3 years, the rudimentary arch was found in 56 of the 60 prints examined The adult form of the arch was discernible at between the ages of 4 and 5 years It could be noted that until this time the foot of an infant was pliable and inverted, and contained copious deposits of fat After this period the arch assumed rigidity and the foot exhibited characteristics of maturity

The author examined about 200 fetuses The smallest measured 8.5 mm in length and the largest had reached full term No discernible differentiation of the hands and feet could be made until the fetus reached the age of 6 weeks At this time digits appeared in both the hands and feet The digits were radially divergent with abduction of the hallux and the pollex At the eighth week or in the 28 mm fetus, the heel had appeared and the foot assumed an angle with the axis of the leg

The dissection of the feet of many fetuses disclosed the longitudinal arch to be fairly complete when the heel appeared fully developed (in 8 weeks) Although some of the tarsal bones were still in the cartilaginous state the skeletal components of the arch had achieved a well defined outline Other pertinent ontogenetic data were the average length of the tarsal bones in an embryo of 20 mm (1) the average length of the heel was 21 per cent of the length of the foot, (2) that of the tarsus was 44 per cent of the length of the foot, (3) that of the metatarsus, 26 per cent, (4) and that of the phalanx, 16 per cent of the length of the foot

Since the author has confined his exhaustive studies to barefooted patients, he has arrived at the conclusion that, on the whole, the arches of the barefooted do not differ from those of persons who wear shoes The arches of the latter may be lower with slight abduction of the forefoot Evidence has been presented that the real factors in the maintenance of the arch are the bony configuration on the medial aspect of foot and the strong ligaments

Examination of the feet of primate animals have shown the stigmata of Wolff's law With the changing of the mode of living, manner of locomotion, and discard of arboreal existence, the shape of the feet of these animals is constantly approximating that of man In the case of the gorilla in upright position the similarity is still closer to man, whose terrestrial habitation has governed the present configuration of his heel, the longitudinal arch, the large tarsal bones, and the relatively small forefoot

SAMUEL L. GOVERNALE, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

On the Treatment of Varicose Veins by Ligation of the Saphenous Vein and Injection in Both Central and Peripheral Directions According to Ollonqvist's Method V. LUOMIOSKI *Ann. chir. gën. fenn.* 1918, 37, 207

The author analyzes the treatment of varicose saphenous veins, in 340 patients, by the method of Ollonqvist. The technique consists of isolating the greater saphenous vein in the upper part of the thigh—the site being that at which an impulse is detected when the distended vein is tapped in the leg or lower thigh—and slowly injecting 2 c.c. of 20 per cent sodium chloride solution proximally, then 5 to 10 c.c. of the same solution quickly, distally. The vein is ligated after each injection, and then divided.

The immediate results of treatment were good. In 57 per cent of cases occlusion of the veins occurred after a single injection, and in 43 per cent of cases postoperative injections were necessary. Undesirable effects were (1) pain which occurred locally, and with a peripheral radiation in most cases, (2) periphlebitis in 2.6 per cent of cases, (3) wound infection in 0.4 per cent, (4) postoperative hemorrhage from the central stump in one case, (5) necrosis of the skin from leakage of the sclerosing solution from the vein in rare instances, (6) brown pigmentation along the course of the injected vein in many cases. No cases of pulmonary embolism occurred.

In a follow up of 133 patients who had undergone treatment from 2 to 9 years previously (a total of 210 ligations), evidence of recurrence was observed in 120 (57%), the remaining patients were free of recurrence. Seventy-five per cent of patients with recurrences had recanalization of all or most of the saphenous vein, and the chief cause of recanalization and recurrences is to be found in insufficiency of the deep communicating veins.

The author believes that the great advantage of the sclerosing method of treatment is the freedom from embolic complications. In a collected group of 1,471 operations, only one doubtful case was observed.

EDWARD H. CAMP, M.D.

The Etiology of Leg Ulcers and Their Treatment by Resection of the Popliteal Vein GUNNAR BAUER *J. internal chir.*, Brux., 1948, 8, 937

The author believes that a previous thrombosis is the commonest cause of the lower leg syndrome. This syndrome is characterized by chronic edema of the lower leg, pain of a dull bursting character, skin lesions in the form of constricting bronze-colored induration, and typical ulcers.

In an effort to discover the causative factors of these ulcers in patients who have not previously had a thrombosis, careful studies were made of 100 patients with varicose veins or leg ulcers. Retro-

grade injections of the femoral or great saphenous veins were made with the use of 20 c.c. of radio opaque media, and roentgenographic studies were carried out. These roentgenograms presented two characteristic pictures. Group 1 comprises 45 cases demonstrating a normal femoral vein with competent valves. Group 2 comprises 55 cases showing the entire femoral and popliteal veins, the deep veins of the leg and, at times, the subcutaneous varicosities to be filled with the contrast material. The author considers this to be a demonstration of a pathological femoral and popliteal vein, with incompetent valves, affording the opportunity for a retrograde flow of blood. In the latter group were found principally the cases with the leg syndrome. The varicosities in group 1 were rarely symptomatic and usually required only high resection of the great saphenous vein, preferably combined with the retrograde injection of a sclerosing solution.

To further study the pathological physiology in deep venous insufficiency, determinations of the pressure in the popliteal vein were made. It was found that in all the veins of the lower extremity a hydrostatic pressure exists that at any given point is roughly equal to, or just below, the weight of a column of water extending vertically from the point of measuring to the level of the heart. When the vein is obstructed distal to the site of measurement there is a greater rise in the cases of proved valvular insufficiency of the femoral vein. It is believed that the ortho-static venous overloading is the cause of the bursting pain almost always complained of by these patients, and that this condition probably leads to the edema.

Evidence based on phlebographic studies is presented to show that a frequent cause of the lower leg syndrome is thrombosis, and 25 such cases are reviewed. Thirteen of these showed evidence of recanalization, which, in turn, implies that the vein valves have been permanently destroyed. The remainder have large satellite femoral veins which bypass the thrombotic areas and produce, in effect, a similar situation.

Thirty cases were observed in which the femoral insufficiency was not caused by thrombosis. These presented a different picture. Microscopically there is a low degree of phlebosclerosis. There is probably a resultant loss of elasticity of the vein wall and valvular incompetence. A marked hereditary influence was found. The author believes that since exact knowledge is lacking, this group should be called idiopathic.

Interruption of the popliteal vein by means of ligation and segmental resection is advocated as the logical treatment, in preference to the higher ligation recommended by Linton and Hardy. The objection to high ligation is that the femoral vein below this level is often filled up with blood from

muscle veins or incompetent satellite veins, and the back pressure on the lower leg is maintained. Fifty-four such operations have been performed at the Mariestad Hospital, in Sweden. The immediate results were good. Twenty-four patients were followed up after a period of 3 to 14 months and the bursting pain had disappeared in all, edema remained in 4, induration in 10, and ulceration in 2.

LEROY J. KLEINSASSER, M.D.

Management of Venous Thrombosis and Pulmonary Embolism Following Injury to the Extremities

FRED B. AURIN and LOUIS G. HERRMANN *Am J Surg*, 1948, 76: 586

The general incidence of venous thrombosis in patients who have sustained injury to the legs is almost 12 per cent as compared with 2 per cent of hospitalized surgical patients in the Midwest. Such clots usually occur in the large veins of the traumatized extremity, or in the pelvic veins in cases of pelvic fractures.

Regular and frequent examination of the thigh, calf muscles, and feet of all patients is essential in the diagnosis of initial phases of venous thrombosis. Promoting venous return from the legs and pelvis is an excellent method of prophylaxis against thrombosis and embolism, thus, good heart action, activity of the muscles of the extremity to pump blood along the vessels, and the gravitational effect of slight elevation of the foot of the bed are important features in the prevention of this complication.

Once thrombosis has been established, treatment must be designed to limit extension, prevent embolism, and correct local impairment of venous circulation in the affected extremity. The author uses heparin and dicumarol as the primary measure, followed by ambulation when local signs have subsided. Such anticoagulant therapy is maintained for 10 to 14 days unless the patient is confined to bed because of the primary disease, in which case dicumarol is administered to maintain a prothrombin concentration of from 30 to 50 per cent of normal.

EDWARD H. CAMP, M.D.

The Value of Transmetatarsal Amputations in the Management of Gangrene of the Toes

WESLEY FURSTE and LOUIS G. HERRMANN *Arch Surg*, 1948, 57: 497

Since 1934 transmetatarsal amputation has been performed for gangrene in 91 cases with a follow-up in 85. The patients with cellulitis in addition to gangrene were first treated with penicillin until the infection subsided. Inhalation anesthesia was most often used. All the amputation wounds were left open except 1 in which a partial closure was done. However, more tissue was left on the plantar surface than on the dorsum of the foot in order that the final closure would provide a long plantar flap. Secondary procedures such as the application of a

TABLE I—RESULTS WITH TRANSMETATARSAL AMPUTATIONS

Disease	Results for amputations with adequate follow up						Number of amputations without adequate follow up
	Excellent	Good	Fair	Poor	Questionable evaluation	Total	
Gangrene diabetes	9	6	4	21	1*	41	1
Gangrene arteriosclerosis	7	1	1	12	5†	26	3
Gangrene frostbite	8	3	0	1	0	12	1
Gangrene osteomyelitis	1	0	1	0	0	2	1
Gangrene arterial embolism	1	0	0	0	0	1	0
Indolent ulcer neurotrophic	0	0	1	1	0	2	0
Gangrene thromboangiitis obliterans	0	0	0	1	0	1	0
Total						85	6

*The 57 year old diabetic white woman considered to have a questionable result died 8 days postoperatively of a myocardial infarct demonstrated at autopsy.

†The patients with arteriosclerosis considered to have questionable results were as follows:

1. A 74 year old white man with an ulcer of his stump who died 7 months after the transmetatarsal amputation because of probable carcinoma of the stomach.
2. A 58 year old white man who died 1 month after operation without definite determination of the cause of death.
3. A 58 year old Negro with a well healed stump for 6 25 months postoperatively who suffered frostbite and required a low leg amputation.
4. A 68 year old white man who died 1 month postoperatively with bronchopneumonia.
5. A 67 year old white man who died 2 weeks postoperatively with pneumonia.

free graft to the granulating stump were frequent. In the cases in which good healing was obtained the patients had little difficulty in standing or walking on the shortened foot. There was no phantom limb pain.

The results were best when the gangrene was due to frostbite. On the other hand, in the presence of intrinsic arterial disease (thromboangiitis, diabetes, and arteriosclerosis) only 36 per cent of the results were classified as good or excellent. The details of the follow up are given in Table I, above.

The hospital mortality in the diabetic and arteriosclerotic group was 14 per cent, which is lower than the 22.7 per cent for major amputations in diabetes at the same institution, and 23.9 per cent in arteriosclerosis obliterans without diabetes.

The authors conclude that the operation is safe and is rarely associated with phantom limb pain, but there must be a judicious selection of cases, the operation must be carefully performed, and preoperative and postoperative care must be adequate.

THEODORE B. MASSFELL, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE, POSTOPERATIVE TREATMENT

Parenteral Use of Water, Dextrose, Electrolytes, Fat, and Vitamins WALTER G MADDOCK *Arch Surg*, 1948, 57 553

This article is a consideration of the therapeutic needs of persons unable or not permitted to take sufficient fluids or food by mouth. In the majority of cases treatment can be kept relatively simple. The use of chemical studies and laboratory data is important and their interpretation is discussed. The body's daily water requirement is discussed particularly in view of its importance to renal function, and the importance of the specific gravity of urine is emphasized and explained.

The use of dextrose solutions for intravenous use should be used specifically for the introduction of water and carbohydrates, but they have no specific value in shock or for replacing electrolyte loss. Protein hydrolysate solutions are indicated in the presence of undernutrition. Five grams of salt given parenterally should be enough for maintenance unless there is evidence of abnormal loss. Probably during the immediate postoperative period (2 days) sodium chloride should not be given.

Dehydration presents a special problem, and deficits should be studied and properly replaced.

Dehydrated patients are usually studied to determine

1 The combining power of plasma carbon dioxide. This test should be augmented by a clinical distinction between "metabolic" and "respiratory" disturbances. If the alteration is the result (partially or totally) of a respiratory disturbance the plasma pH should be determined.

2 Serum sodium

3 Serum potassium

4 Plasma chlorides

5 Blood nonprotein nitrogen

6 Plasma proteins

The symptoms and signs of dehydration are more acute as the deficit develops more rapidly. The manner in which dehydration develops may alter the picture, the dehydration may be due primarily to water loss or to electrolyte loss.

Specific case examples of types of loss and water and electrolyte needs are discussed, including (1) vomiting from pyloric obstruction, (2) vomiting from duodenal, jejunal, or upper ileal obstruction, (3) bile or pancreatic fistula drainage, (4) ileostomy drainage and diarrhea, (5) ketosis of diabetic and nondiabetic origin, (6) nephritis, and (7) burns.

To develop "working approximates" for parenteral therapy a consideration of the history, physical examination, and laboratory studies including the volume and the specific gravity of urine, the hemoglobin and hematocrit values, plasma chloride, pro-

tein, carbon dioxide combining power, and blood nonprotein nitrogen may be needed.

The common and special solutions for parenteral use discussed are (1) isotonic sodium chloride, (2) Ringer's solution, (3) lactated Ringer's solution, (4) hypotonic sodium chloride, (5) hydrochloric acid, (6) ammonium chloride, (7) sodium bicarbonate, and (8) sodium lactate.

Renal insufficiency in dehydration may be due to the lowered filtration pressure caused by dehydration, the presence of actual kidney disease, the lack of water, or both of the latter causes. A good intake of water must be provided.

The daily gastrointestinal loss should be calculated and replaced by parenteral therapy.

The parenteral uses of potassium, fat emulsions, and vitamins are discussed in the light of present information.

The basic information for the administration of nutritional substances is one of the recent great advances, and the ability to maintain a normal environment for the patient's cells has saved countless lives.

W F MONTGOMERY, M D

An Attempt to Evaluate the Different Modern Methods for the Prevention and Treatment of Thromboembolism J P STRÖMBÄCK *Acta chirurgica*, 1948, 97 113

The retardation of venous drainage is a factor of primary importance in the etiology of thromboembolism. Early ambulation after operation is the best method that is known at present for the prevention of thrombosis. The author believes that it should be begun on the day of operation, or not later than 2 or 3 days following the operation.

Dicumarol may have a valuable auxiliary effect. It should be started on the day after operation and the prothrombin percentage should be kept at from 10 to 30 per cent during the entire period of healing. Dicumarol is contraindicated in patients with liver injury, in those having a tendency to hemorrhage, in cases in which control of bleeding from the wound is incomplete, and in certain renal affections.

The ability to diagnose complications of thrombosis early must be developed by both doctors and nurses. The treatment of manifest thromboembolism with heparin supplemented by dicumarol, as early as possible, followed by early ambulation seems to offer the best guarantee of good immediate and late results.

Venous interruption as a prophylactic or therapeutic measure is not dealt with in the present study.

JAMES WEAVER, M D

Reconstruction Following Irradiation Injuries PAUL W GREELEY *Arch Surg*, 1948, 56 741

Radiation injuries may be secondary to necessary treatment for malignancy, may follow overzealous

treatment of cutaneous lesions, may develop in patients with unusually susceptible skin, or they may be due to therapy given with an improperly calibrated machine. Symptoms of x-ray dermatitis are characterized by severe pain, itching, and ulceration. X-ray dermatitis is associated with an obliterative arteritis and hyalinization of the vessels of the involved skin. Subsequently, anemic gangrene or white necrosis with ultimate ulceration follows. The surrounding skin becomes telangiectatic and keratotic. Squamous cell carcinoma may develop in a certain percentage of the latter areas. Because the pathologic reaction is irreversible, permanent cure can be obtained only when the involved tissue is excised up to the area of the normal blood supply. Reconstructive surgery is required for the completion of treatment. The defect may be closed by primary suture with undermining or by a skin graft or skin flaps.

BENJAMIN G. P. SHAFIROFF, M.D.

ANTISEPTIC SURGERY, TREATMENT OF WOUNDS AND INFECTIONS

The Treatment of Open Traumatism of the Hand in Miners (Tratamiento de los traumatismos abiertos de la mano en los mineros) VICENTE VALLINA GARCÍA. *Cirug. apar. locomotor*, 1948, 5: 450

The importance of functional integrity of the hands in miners cannot be exaggerated, and 10 years of experience in the care of lesions of the hands has convinced the author that, from the standpoint of subsequent working capacity, an open fracture of a phalanx or metacarpal may be as important as a fracture of the femur, spine, or pelvis. The permanent incapacities observed after more or less important injuries to the hand, the customary resistance to treatment of certain posttraumatic sequelae, and the passive resistance of the patients, who see in invalidity their liberation from the hard and dangerous work in the mines, have stimulated the author's interest in the treatment of these cases.

The surgical procedure to be followed in open traumatism of the thumb or its metacarpal is totally different from that of the rest of the hand. Functionally, the thumb is the equivalent of half of the hand, and the working future of the patient, to say nothing of the resources of the insurance company, will depend on the behavior of the surgeon, whose constant preoccupation should be to conserve the thumb and never remove it before having done every thing possible to keep it, as even a rigid thumb may be very useful to its host.

In traumatic amputation of the thumb, treatment consists only of cleansing the wound with physiologic salt solution, ligating some artery if necessary, and awaiting cicatrization. If the amputation runs through the metacarpophalangeal joint, the skin may be sutured if it is not lacerated.

It may be stated in general that in all other open lesions of the hand the patient is kept in bed for the first 8 days, a sulfonamide, preferably cibazol or

sulfathiazole, is administered for from 2 to 4 days, and an abduction splint and a plaster cast are used, the latter extending from the upper part of the forearm to the indicated part of the involved finger.

In open fracture of the phalanges of the thumb, if the patient is seen within 6 hours of the accident, thorough cleansing of the hand is followed by conservative treatment and closure of the wound, if more than 6 hours have elapsed, the wound is left open. In infected fracture, the necessary incisions are made, the fracture is reduced, a vaseline gauze dressing and a closed plaster cast are applied, and 30,000 units of penicillin are given every 3 hours, in these cases the patient is kept in bed up to 2 weeks after disappearance of the fever. If sequestrectomy is necessary after healing, it is performed with minimal traumatism and the avoidance of curettage, which often causes chronic and rebellious osteitis.

Open fractures of the first metacarpal are treated like those of the thumb, particular care being taken in the reduction of the articular fracture of the upper extremity of the bone.

Wounds of the thumb must be treated with the same precautions as those used in fractures because they give rise to the same consequences if they are left alone or incorrectly treated.

In open fracture of the phalanges of the other fingers, the problem is conservation of the function of the hand which is jeopardized by the presence of a finger that impedes the normal movements of the others. Any open fracture associated with extensive detachment of the skin, section of the tendons, lesion of the palmar collateral vessels, or involvement of a joint, must be treated by amputation at the metacarpophalangeal joint. In the other noninfected open fractures the wound is resected and, of necessity, left open in most cases. The digital splint is arranged so that the metacarpophalangeal joint is in 45 degree flexion, the first interphalangeal joint in 90 degree flexion, and the second in 45 degree flexion. From the first day, the nonimmobilized fingers must be moved from maximal extension to maximal flexion, the movements being performed several times each hour.

Infected fractures of the fingers are treated by amputation at the metacarpophalangeal joint.

In open fractures of the second to fifth metacarpals, among which those of the second are more frequent, consolidation is easily obtained even when immobilization is not very strict, because the interosseous muscles help to retain the fragments in place. From the first day, all fingers must be moved to the fullest extent possible. If the fracture is associated with a severe lesion of the skin or section of the flexor tendons, it is preferable to amputate the finger at the metacarpophalangeal joint, or through the focus of fracture if the latter is distal. Fracture of the head of the fifth metacarpal must be treated by immediate amputation at the focus of fracture.

Infected wounds of the fingers with involvement of the tendon sheaths or joints, and diffuse phlegmon of a finger with limited movements of the other

fingers must be treated by prompt amputation at the metacarpophalangeal joint, the wound being left open. The other fingers must be actively mobilized to their full extent of flexion and extension. In contused wounds with detachment of the soft tissues in the palm and exposure or laceration of the tendons it is best to amputate. In tendosynovitis which does not justify amputation, incisions are made on the borders of the fingers.

In recent wounds with section of the tendon, the latter is sutured only when the wound is clean and has been made with a cutting instrument, otherwise, the wound only is treated and suture of the tendon is given attention later. Sectioned extensor tendons of the back of the hand are sutured under these conditions, those of the back of the fingers are sutured and the fingers are immobilized in semiflexion because complete extension impedes flexion of the remaining fingers. If both flexor tendons of the fingers are cut, it is sufficient to suture only one, but when the tendon section is associated with fracture of the finger, amputation is performed.

RICHARD KEMEL, M D

The Role of Chemotherapy in Wounds and Surgical Infections. A Study of the Significance of Gram-Negative Pathogens in Fresh Trauma and Chronic Infections. DOUGLAS ACKMAN and FREDERICK SMITH. *Am J Surg*, 1948, 76 483

Gram-negative pathogens are not very common contaminants in fresh trauma or in surgical infections. They are found most often in lesions of the lower extremity. They tend to persist, although their presence rarely causes delay in healing. Despite their persistence, these organisms show almost no tendency toward invasion in fresh trauma when the circulation is adequate. Even in cases of gross contamination with gram-negative organisms in pre-existing surgical infections, revision grafts are almost equally immune when local and general physiologic conditions are satisfactory. These local conditions are well maintained by occlusive dressings, infrequently changed. There is no clinical evidence of a symbiotic relation between gram-negative and gram-positive organisms.

Topical application of creams of sulfathiazole, penicillin, and streptomycin have all failed to eliminate gram-negative pathogens in fresh trauma and surgical infections. Streptomycin has caused "fast" organisms in four instances. Some more recent experiences with this drug have been more satisfactory. When invasion by gram-negative organisms does occur, intramuscular streptomycin has given very encouraging results in the few cases so far observed.

JAMES WEAVER, M D

Penicillin Therapy with Prolonged Interval Dosage Schedules. W A ALTEMEIER. *Ann Surg*, 1948, 128 708

A study was made of the dosage of penicillin in the treatment of 161 selected cases of established surgical infections in an effort to determine the

clinical effectiveness of the single intramuscular injection of larger doses of penicillin in aqueous solution every 8 to 12 hours.

The clinical results obtained in the author's series of selected cases were very gratifying and were probably indistinguishable from those anticipated with injections of penicillin at 3 or 4 hour intervals with the possible exception of 2 cases of severe and extensive infections caused by the hemolytic streptococcus. The experimental and clinical evidence has indicated that for some unknown reason the antibacterial effect of penicillin persists for a considerable length of time after its disappearance from the circulating blood. Although the author's series of 161 cases was relatively small from which to draw any conclusions, it appeared that the maintenance of a more or less constant blood level is probably unnecessary for efficient therapy in the human being. A limited clinical experience revealed that the intramuscular injection of an aqueous solution of penicillin containing from 100,000 to 200,000 units every 8 to 12 hours was an efficient and effective method of chemotherapy in susceptible infections of moderate severity. This method overcomes the disadvantages and inconveniences of the 2 to 4 hour dosage schedule to a large extent and has not resulted in any increased tendency of the bacteria to develop resistance to penicillin.

This dosage schedule of administration of only 2 or 3 injections per 24 hours decreases the task of the nurse and releases part of her time for other more necessary nursing duties. The 8 and 12 hour dosage schedule is advocated at present by the author only in susceptible infections of moderate severity or less, until further experimental information is gathered.

JOHN E. KARABIN, M D

Re-Evaluation of Penicillin Dosage Schedules. W A ALTEMEIER. *Arch Surg*, 1948, 57 396

The clinical effectiveness of intramuscular injections of 100,000 units of aqueous penicillin administered every 8 hours and of 150,000 units administered every 12 hours was studied. A single intramuscular injection of 100,000 units of penicillin gave a concentration of 0.03 units per 1 ml of serum for 3 hours, and in 11 per cent of the patients that concentration was maintained for almost 7 hours. The level of 0.03 units is generally accepted as the therapeutic level.

Five different strains of pathogenic hemolytic *Staphylococcus aureus* showed a definite inhibition of growth for 24 hours when exposed in vitro to 2 units of penicillin per 1 ml of medium. Clinically, equal therapeutic benefit was obtained from penicillin when administered intramuscularly every 8 hours as when administered every 3 hours. With penicillin susceptible infections in human cases a constant blood level of the antibiotic was found to be unnecessary since its effectiveness persisted even after the blood penicillin levels were no longer measurable. However, in severe and fulminating infections the 3 or 2 hour schedule was recommended.

BENJAMIN G. P. SHAFIROFF, M D

Anthrax 36 Human Cases of the External Type Treated Successfully with Penicillin A C LA-BOCCETTA *Am J M Sc*, 1948, 216 407

Anthrax in humans is seen principally as an occupational disease of veterinarians and workers in the wool and leather industries. As no methods for active prophylaxis have been developed, prevention depends largely upon the control of the infection in animals and the employment of general hygienic and sanitary measures. Reports of the Philadelphia Health Department show no tendency of the incidence of the disease to decrease. During the period from 1904 to 1947 there were reported 433 cases within the city with a mortality of 11.5 per cent. Specific antiserum, bacteriophage, and neoarsphenamine have been employed in the treatment of anthrax.

During the period from 1943 to 1947, thirty-six patients with uncomplicated cutaneous anthrax were treated with sodium penicillin in doses of from 100,000 to 200,000 units daily. Bacteriological confirmation of the diagnosis was obtained by smear or culture in 83.4 per cent of cases, in 6 cases (16.6 per cent) the diagnosis was not confirmed bacteriologically, but in the author's opinion the characteristic appearance of the lesions left no doubt of the clinical diagnosis. Of the bacteriologically positive cases 90 per cent became negative after 72 hours of treatment with penicillin. Positive cultures or smears were obtained in 2 patients after 6 and 15 days respectively. In many cases it was seen that the lesions continued to spread and the edema increased for a period of from 24 to 36 hours after treatment had been instituted, a phenomenon commonly observed when patients previously were treated with antiserum. No local treatment other than dry dressings and occasional splinting was used. The author concludes that intramuscular penicillin may be successfully used in the treatment of cutaneous anthrax.

WAYNE FIELD CAMERON M D

Treatment of Tetanus HOMER M SMATHERS and MILTON R WEED *Arch Surg*, 1948, 57 291

A plan of treatment of tetanus was formulated on the basis of experiences with 82 cases, in some of which intocostin and d-tubocurarine were used. In this series 36 deaths occurred within 48 hours of admission. It was found that enough antitoxin should be given to neutralize the unfixed tetanus antitoxin. When a tetanus producing focus was found it was eradicated by débridement.

Intocostin used for the control of muscle spasm was of temporary benefit and was associated with hypersecretion in the laryngotracheal tubes and a profound fall in the blood pressure. The use of d-tubocurarine suspended in wax and oil produced a prolonged curare effect with fewer side reactions. The dose varied from 0.6 ml to 2.0 ml daily. For sedation respiratory depressants were avoided, paraldehyde, chloral hydrate, or ether in oil were found to be most satisfactory. The plan of treatment follows.

Preoperative

- 1 Tetanus antitoxin sensitivity tests—skin and conjunctival
- 2 D tubocurarine in wax and oil, 1 c c intramuscularly
- 3 Tetanus antitoxin, 60,000 units intravenously
- 4 Tetanus antitoxin, 10,000 units locally
- 5 Preoperative medication

Operative

- 6 General anesthesia
- 7 Tetanus antitoxin 20,000 units intrathecally
- 8 Débridement of wound

Postoperative

- 9 Sedation—chloral hydrate, paraldehyde, ether
- 10 Tetanus antitoxin, 5,000 units daily for from 5 to 10 days
- 11 D tubocurarine in wax and oil intramuscularly daily to tolerance
- 12 Penicillin, 50,000 units intramuscularly every 3 hours
- 13 Maintain nutrition orally and parenterally
- 14 Available at bedside—nasal oxygen, laryngoscope, endotracheal tube, aspirating apparatus

ANESTHESIA

Certain Factors Influencing the Percentage of Oxygen in Mixtures of Nitrous Oxide and Oxygen

JAMES H CROWLEY, ALBERT FAULCONER, JR, and JOHN S LUNDY *Current Res Anesth*, 1948, 27 255

The authors report a study of certain factors which govern the percentage of oxygen available to a patient when mixtures of nitrous oxide and oxygen are administered by a circle-absorption semiclosed technique.

A description is given of the techniques used in this study.

Observations were made with the use of mixtures of nitrogen and oxygen which were found to behave, with certain limitations, in a manner similar to mixtures of nitrous oxide and oxygen.

The percentage of oxygen available to the subject was found to be much less than the percentage of oxygen delivered to the machine when slow total rates of flow were used. The more rapid the total rate of flow the more nearly did these percentages approach equality.

An important factor in the reduction of the percentage of oxygen available to the patient was found to be dilution of the nitrogen of the "bag mixture" during the first few exhalations of the subject.

Recommendations were made by which the dangers of incorrect estimation of the oxygen might be eliminated.

SURGICAL INSTRUMENTS AND APPARATUS

New Incisions and Revised Techniques in Peripheral Surgery EMIL SFLETZ *West J Surg*, 1948, 56 565

The central theme of the present article is that of the surgical principles and problems involved in obtaining good exposure for definitive treatment of

peripheral nerve injuries. A series of diagrams and photographs is presented to illustrate various incisions and approaches advocated by the author for the exposure of nerves in the extremities. The conclusions are based on experience gained from the study and operative repair of 2,037 nerve injuries during the war years.

The incisions and surgical approaches employed by the author are based on principles involving a more direct surgical approach to obtain adequate exposure of the injured nerve. The approach is made through fascial planes rather than through muscle substance. If it becomes necessary to incise muscle tissue, the incision should always be made in the direction of its fibers. When a muscle must be divided it is severed only at its point of fascial attachment so that it may be easily repaired. Skin incisions which are perpendicular to flexion creases must be avoided since a traction scar will invariably result. Not only is the skin involved in the production of contractures, but there is involvement of the subcutaneous tissues and fascial layers as well.

In cases in which the surgical exposure involves a joint area, the incision should generally be an interrupted one. This may be accomplished in one of two ways: when the involved joint is in the cubital or popliteal space, a Z-shaped incision, as described by the author, is used, when exposure is needed on either side of a joint in a limited area, as in the wrist, the incision is interrupted and the area between is tunneled so as to provide adequate exposure.

ORVILLE F. GRIMES, M.D.

A Simple Method of Estimating Blood Flow with Special Reference to the Circulation in Pedicled Skin Flaps and Tubes. WILFRED HYNES. *Brit J Plast Surg*, 1948, 1: 159

The author states that a precise knowledge of both the arterial supply and the venous drainage of a pedicled flap or tube at each stage of its transfer has the following advantages:

1. The periods of waiting between the stages of the transfer can be reduced, sometimes by half. Besides shortening hospitalization, it reduces the

amount of scar tissue under the flap or inside the skin tube so that the tissues remain soft and pliable and require practically no trimming at the new inset.

2. Pedicles can be divided with confidence, and tiresome scar-producing division by delay can be avoided.

The methods advocated by Lewis, Douglas and Bucholtz, Douglas and Millican, and Lange and Boyd are discussed briefly.

The author's method, which he believes is simplest and gives the most complete information regarding the circulation, consists of the injection of 1/25th of a grain of atropine sulfate, dissolved in 0.2 c.c. of sterile water, into selected sites on the flaps or tubes. If a tubed pedicled flap is to be tested, a bowel clamp with the blades protected by rubber tubing is placed firmly across the end to be detached and the atropine injected just below it. If an open or direct flap is to be tested, a tourniquet is placed around the donor extremity and the injection is made in the most distal portion of the flap. By timing the appearance of three specific effects of atropine in the circulation, an estimation of the blood flow in a flap can be obtained.

Tachycardia is the most reliable sign of atropine absorption; 1/25th of a grain injected subcutaneously in the face of an adult raises the pulse rate from 72 to 104 in a period of 10 minutes and to 118 in a period of 20 minutes.

Changes in the pupil do not necessarily occur early, and a better test is the inability to read an ordinary newspaper. Inability to focus properly will occur in from 15 to 45 minutes.

Dryness of the mouth starts as a tingling sensation in the lips or in the back of the throat and is quickly followed by a feeling of increasing dryness in the mouth, throat, and larynx within 15 minutes after injection of 1/25th grain of atropine subcutaneously in the face.

Accurate timing of the appearance of the above three signs of atropine absorption, following its injection into a flap or tubed pedicled flap, will result in a reliable estimation of the blood supply both qualitatively and quantitatively.

EARL H. KLABUNDE, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

An Evaluation of Phlebography of the Normal Lower Extremity BERNARD S EPSTEIN, MILTON G WASCH, and LEO LOEWE *Am J Roentg*, 1948, 60 650

Acting upon their belief that the value of phlebography cannot be properly delimited until the range of normal variation has been thoroughly studied, the authors made phlebograms of a lower extremity in each of 35 patients who were free of any clinical evidence of pre-existent venous disturbance. The patients selected were those in whom intravenous urography was being done. Twenty cubic centimeters of either diodrast or neo-iopax in 50 per cent solution were injected within 60 seconds into a superficial vein on the dorsum of the foot or over either malleolus, with the leg placed in slight inversion. Immediately upon completion of the injection roentgenograms (made in quick succession) were centered, respectively, below the knee joint, just above it, and below the groin. In the last 8 patients, roentgenographs were taken in the lateral as well as the antero-posterior position, for better visualization of the leg veins. One-half of the first 20 examinations were conducted with a compression of 30 mm of mercury maintained about the calf, but when no difference could be observed in the phlebographic patterns obtained with and without compression, it was concluded that compression had not been of assistance in visualizing the deep venous system, and the practice was discontinued.

The authors review the normal anatomy of the venous system of the lower extremity, both superficial and deep, as a basis for evaluation of their radiographic observations. The latter consisted in an attempt to identify each vein visualized, and a review of the general venous pattern. They found that the lesser saphenous vein was excellently visualized in 6 patients, partially visualized in 26 patients, and not seen at all in 3. The long saphenous vein was well visualized in 10 individuals, partly visualized in 16, and invisible in 9. Visualizations of the deep veins of the leg were uniformly poor. In no instance was clear demonstration of paired anterior and posterior tibial and peroneal veins, as 6 well filled channels, achieved on the same patient. Almost all patients had some degree of opacification of a single anterior or posterior tibial or peroneal vein. Variations in caliber, and sudden transitions from filling to nonfilling were common. Occasionally a few transverse communicating channels were seen. The proximity of the channels of peroneal and anterior tibial veins made identification difficult if only one of these channels, or a part thereof, was visualized. Deep veins were somewhat better visualized in the antero-posterior view, while superficial veins and veins of the calf were better seen in the lateral projection.

The pattern formed by the latter appeared inconsistent. Overlapping of the various systems further complicated interpretation.

The popliteal vein was excellently visualized in 21 patients, and partially visualized in 14. The femoral vein was well seen in 20 individuals and was only irregularly filled in 12, in 3 cases it was not seen. Filled collateral channels were occasionally demonstrated, and in 2 patients the deep femoral vein was opacified.

The authors comment that incomplete or irregular filling, or absence of filling of the leg veins has been considered by some workers as indicative of thrombosis, but they conclude from their work on these 35 clinically normal individuals that there is need for great circumspection in evaluating phlebographic patterns obtained by the usual techniques, particularly in the leg. They believe that phlebography cannot be considered a proved aid in the diagnosis of thrombophlebitis because the inconstancy of the patterns found in normal patients often makes it impossible to differentiate between the normal and abnormal.

LILIAN DONALDSON, M D

The Possibility of Venous Embolism in the Course of Hysterosalpingography (Sulla possibilità di embolie venose in corso di isterosalpingografia) MAURO PIEMONTE and PIERO PARACCHI *Radiol med*, Milano, 1948, 34 682

Approximately 30 cases of venous embolism following hysterosalpingography have been published in the literature. In the majority of cases the course is asymptomatic or only slight symptoms such as cough are present. Occasionally, however, pain in the hypogastrium, the formation of multiple emboli and infarcts in the lungs, obstinate cough, hematemesis, pain in the chest, anxiety, and rise of temperature may be observed. If the iodized oil reaches the left part of the heart, multiple cerebral emboli may form, leading to mental depression, loss of memory, and focal symptoms, such as amaurosis.

As a rule, the clinical course of venous emboli formed by iodized oil is favorable. Only 2 fatal cases have been reported.

Two factors favor the formation of emboli in the course of hysterosalpingography: (1) pre-existing disruption of the continuity of the endometrium (a) physiologic, namely, during the immediate post-menstrual period, and (b) pathologic, caused by traumas or neoplasms, and (2) excessive endouterine pressure. Even the moderate pressure under which iodized oil is injected may lead to disruption of the endometrium and entry of the radiopaque substance into a vein, when the resistance of the uterine mucosa is lowered, the tubes are occluded or had been removed operatively.

The author employed hysterosalpingography in a woman, aged 55, who was admitted with complaints of slight uterine bleeding. The clinical diagnosis was

fibromyoma After an injection of 15 c.c. of iodized oil into the uterine cavity, the right uterovaginal and pampiniform plexus and the left uterine vein were visualized. Roentgenograms of the chest demonstrated a uniform distribution of oil throughout the lungs. A sensation of constriction over the chest, dyspnea, profound asthenia, cyanosis, moist cough, headaches, and subfebrile temperature developed.

Two months later subtotal hysterectomy and bilateral salpingo-oophorectomy were performed. The atrophy of the mucosa overlying the fibroma probably facilitated the entry of the oil into the veins.

JOSEPH K. NARAT, M.D.

Irradiation in Cancer of the Tongue CHARLOTTE P. DONLAN *Am J Roentg*, 1948, 60 511

The author reviews 83 proved cases of carcinoma of the tongue in patients who were treated in the Radiotherapy Department of Presbyterian Hospital, in New York, during the period between 1929 and 1946. The treatment of the tongue lesions consisted of the interstitial implantation of radium needles in the tongue plus roentgen irradiation, and roentgen irradiation alone. An attempt was made to give 8,000 gamma roentgens or more to the tongue when interstitial radium needles were used. Supplementary roentgen therapy was given if the radium dosage was less, or if the lesions tended to persist after the usual dosage had been given. When roentgen therapy alone was used, the aim was to give a tumor dose of 5,000 to 6,000 roentgens. The cases were classified as operable cases, inoperable cases, and borderline cases.

Twenty-two cases were classified as operable. The average duration of symptoms in this group was 9.25 months. Ten of 19 patients survived for over 5 years, a survival rate of 52.6 per cent. (Three patients were admitted after 1942 and therefore could not be included in this percentage rate.) Seven of the 10 patients who survived had neck resections, 4 of which were bilateral. Of these 4, only 1 patient showed histopathological evidence of disease in the nodes.

Nine cases were classified as borderline. The average duration of symptoms was 7.4 months. None of the patients survived 5 years, although 2 cases are too recent to have attained that survival period, both patients are living and well. In 1 patient a unilateral neck resection was performed 5 months after treatment of the tongue lesion, 1 had a pulmonary and esophageal metastases, and 1 had metastases to the femur.

There were 34 inoperable cases in which the average duration of symptoms was 7.5 months. The condition of the nodes was mentioned in 30 histories and of these, 12 had palpable nodes on admission. Only 4 of these 12 had neck dissections.

Two patients had unilateral neck dissections before receiving treatment for the primary lesion. In both of these cases the primary lesion was in the base of the tongue and difficult to diagnose.

Five of 23 patients lived 5 years or more, a survival rate of 21.7 per cent. Eleven cases were admitted after 1942 and therefore could not be included in the percentage.

Eighteen patients with inoperable lesions were treated by roentgen irradiation alone. The average duration of their symptoms was 5.8 months. In 2 of these 18 cases, pulmonary metastases developed.

Eight patients (44.5 per cent) had palpable nodes on admission. No neck dissections were done.

Two of 13 patients (16.9 per cent) lived over 5 years. Six patients had been admitted too recently to be included in this percentage group.

Among the 55 cases admitted up to, or before, 1942, there was an over-all 5 year survival rate of 30.9 per cent.

FRANK L. HUSSEY, M.D.

The Roentgen Treatment of Carcinoma of the Larynx by the Concentration Method (El tratamiento radiológico del carcinoma laríngeo por el método de la concentración) RAÚL MAYER *Diagn Med*, B. Air, 1948, 20 2210

The author irradiated 216 patients with carcinoma of the larynx. Of this group, 123 were treated by radiation alone. The remaining 93 were treated for recurrences that followed surgery.

The Coutard method was used exclusively until 1942. The Coutard-Cutler or "concentration method" was developed soon thereafter and has been used since.

The Coutard method for treating laryngeal cancer was first used in 1933. During that year and in 1934, 18 patients were treated and of these, 3 were living and well at the end of 5 years (15.6%).

From 1935 up to and including 1937, 32 patients with inoperable laryngeal cancer were similarly treated, and of these, 8 (25%) remained well for from 5 to 7 years.

During the period from 1938 up to and including 1941, 38 additional patients were irradiated by the Coutard method. Of the latter, 9 (23%) remained well for 5 years.

The Coutard technique first used roentgen rays generated at 185 kV with 5 ma. In July of 1938, the voltage was changed to 200 kV with 10 ma. The distance remained constant at 70 cm. with 2 mm. of copper plus 2 to 3 mm. of aluminum filtration. The fields varied in size from 49 to 144 sq. cm. Usually from 5,000 to 8,000 roentgens were delivered at a rate between 2.5 and 7 roentgens per minute in 6 to 12 days.

The Coutard-Cutler technique was developed in 1942. Roentgen rays generated at 200 kV, delivered at a distance of 70 cm., with a filtration of 2 mm. of copper plus 2 mm. of aluminum plus 3 mm. of bakelite, were used. The milliamperes were varied in order to assure a tube output between 5.5 and 8 roentgens per minute.

Two lateral fields, one on each side of the neck, were treated daily, one in the morning and the other 6 hours later in the afternoon of the same day. The 6 hour interval was decided upon because severe re-

actions developed when a shorter period of time between the daily exposures was used

As a rule two portals (each 100 sq cm) were used, 1 portal being directed into each side of the neck. The smaller or localized laryngeal cancers were also treated through 2 portals, each of which measured 64 sq cm. The fields are gradually reduced in size until they reach a minimum of 9 sq cm in some cases

No attempt is made to treat the involved cervical lymph nodes until the primary lesion has been adequately managed. Thereafter, the nodes are treated, care being taken to protect the previously irradiated areas

The authors deliver 100 roentgens to each of the two fields daily. The daily exposure to each field is increased 25 roentgens until both fields receive 475 roentgens per day, a total of 950 roentgens daily. The treatment is usually completed in 16 days, at the conclusion of which time the patient usually has received 9,350 roentgens. The daily exposure is somewhat less in the presence of severe infection, for which penicillin is used freely

In most instances a dry radioepidermitis develops, which is less severe than the skin reactions usually observed when the old Coutard technique was employed. The authors believe that the "concentration" technique is less exhausting to the patient than the old Coutard technique

During the interval from May, 1942 to October, 1945, the "concentration" technique was used on 35 patients. Of this group, 13 (37.1%) remained well for from 2 to 5 years

EUGENE P. PENDERGRASS, M.D.

Spindle Cell Tumors of the Gastrointestinal Tract

WILLIAM L. PALAZZO and MILFORD D. SCHULZ
Radiology, 1948, 51: 779

The authors prefer the term "spindle cell tumor" to describe those tumors arising from mesodermal tissue, because the usual classification as neurinoma, neurofibroma, leiomyoma, or fibroma becomes so difficult in the malignant tumors

The study is based on 140 cases of histopathologically proved spindle cell tumors of the gastrointestinal tract. They were found in 0.67 per cent of 12,000 protocols of autopsies and in 1.2 per cent of 5,313 surgical records at the Massachusetts General Hospital. Of the total, 9 per cent were located in the esophagus, 65 per cent were located in the stomach, 17 per cent in the small intestine, and 9 per cent in the large intestine. Spindle cell tumors accounted for 2.3 per cent of all esophageal tumors removed in a 16 year period, for 5 per cent of those in the stomach, for 7 per cent of those in the small intestine, and 0.2 per cent of those in the large intestine

Thirty three per cent of spindle cell tumors of the esophagus, and 36 per cent of spindle cell tumors of the stomach were malignant. Recurrence or metastasis, if present, was evident within 4 years, 54 per cent of the patients remained well and free of the

disease for an average of 8 years. In the small bowel, 7 (77%) of the spindle cell tumors were malignant and none of these patients remained free of disease for more than 3 years. Six (86%) of these tumors of the large bowel were malignant and one patient of this group is without disease 5 years after operation

In discussing the criteria for roentgen diagnosis, the authors state that in their experience, smoothly circumscribed intramural tumors without ulceration or marked lobulation are more often benign, or are benign extrinsic lesions. This diagnosis is more reliable in the esophagus than the stomach. However, they conclude that there are no reliable criteria by which benignity of a spindle cell tumor can be recognized in the roentgen examination. In addition, the authors state that these tumors cannot be differentiated from cysts of the esophageal wall, mediastinal cysts, or tuberculous lymph nodes attached to the esophageal wall, aberrant pancreas, and even defects due to vascular anomalies

Some Tracer and Therapeutic Studies with Artificial Radioactivity J. H. LAWRENCE *Brit J Radiol*, 1948, 51: 531

The author briefly discusses the formation of artificial radioactive isotopes by use of the cyclotron and atomic pile. Tracer studies have been conducted upon patients with rheumatoid arthritis by measuring the circulation time of radioactive sodium chloride. It is found that persons with this disease have a reduced circulation time and the uptake of radio-sodium is reduced

Radioactive gold sodium thiosulfate has been given intravenously to rabbits suffering from chemically induced arthritis, as well as to controls. A relatively high uptake was found in the liver, kidneys, and the involved synovial membrane

A discussion of polycythemia vera is presented in addition to the therapeutic application of P₃₂. More than 100 patients have been treated by the selective uptake of radioactive phosphorus in the bone marrow. Two doses of 5 mc each are given intravenously 1 month apart. One course of therapy has usually resulted in the return of the red count to normal, decrease in size of the spleen to normal, or nearly so, and relief of all symptoms of the disease

In 116 cases of polycythemia, the author found the average age of onset was 49, and of 18 patients who died, the average age at death was 67. This series was compared to another series of 163 patients in this country of whom only 36 lived more than 5 years after the diagnosis was made. Previously, the common causes of death were thrombosis in the veins or arteries, cardiac failure, or leucemia. In the present series, thrombosis was rare, perhaps related to the depression of the red cells and platelets as a result of irradiation and return of the blood viscosity to normal, and possibly due also to some other cause

of clotting of the blood Four of this group of patients developed leucemia In 250 patients with chronic leucemia, the average length of life approached 5 years This method of treatment has given results not completely satisfactory, but it is devoid of the usual radiation sickness

The use of I-131 in the treatment of hyperthyroidism and certain thyroid gland malignancies is noted This centers about the selective localization of iodine within the thyroid gland in excess to other tissues Hyperthyroid patients usually do not suffer a recurrence of symptoms and signs after one course of therapy

The author briefly touches upon the surface application of P₃₂ by blotting paper for the treatment of cancers of the skin In addition, the subject of radioactive colloids and labeled compounds as applied to medical research is presented

HORACE G BUTLER, M D

Radioactive Iodine as a Diagnostic Aid for Intrathoracic Goiter G ANSELL and J ROTBLAT *Brit J Radiol*, 1948, 51 552

An intrathoracic goiter is considered by the authors as complete when four-fifths or more is in the thorax, and incomplete if at least one-half of it is palpable in the neck This is further localized by the anterior, lateral, or posterior position

A list of lesions and differential points from a radiological standpoint is presented according to the three positions occupied by an intrathoracic goiter Doubt has existed in some few cases as to the diagnosis of such lesions and radioactive iodine was used for differentiation The authors have administered a tracer dose of radioactive iodine in 5 such cases and include a description of their method and a case report

A counter was built with sufficient lead shielding to stop gamma rays coming from any thyroid tissue in the neck, so that counts from only the chest would be recorded The counter, in spite of its weight, was

made quite mobile and did not support itself upon the patient's chest A diagram of the counter and shield is recorded A lead collimator of 1 inch diameter was used in order to count smaller and more precise areas

Experimentally, it was found feasible to map out the area in which radiation was contained by moving the counter over the area and measuring the activity at various points A lead marker was placed on the chest wall to the left of the manubrium sterni and films were obtained in the posteroanterior and lateral positions

Twenty-four hours before counting, 90 microcuries of I-131 were given The counts were taken over various areas of the anterior chest and neck, and the areas were marked by a circle of adhesive plaster containing a number and the number of counts A photograph was taken at the completion of counting and the lead marker served to correlate the position of the counts with the roentgen illustration

The number of counts per time interval was plotted against the distance of the source from the central position of the axis of the counter, and an analysis of the results was made in order to determine the position of the goiter The contour of the thyroid determined from the measurements agreed fairly well with the roentgenogram in spite of some impairment of accuracy The curvature of the chest prevented the collimator from being flush with the chest wall in some areas, which caused a degree of error Other errors may be created by an intrathoracic goiter of nonuniform consistency or of varied distance from the chest wall

The authors point out that the majority of intrathoracic goiters will have sufficient uptake to be outlined Large cysts within the mass may alter the estimation of contour It is pointed out that only 15 per cent of thyroid carcinomas take up radioactive iodine and therefore such lesions could not be ruled out by this procedure HORACE G BUTLER, M D

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Parenteral Feeding of Protein ROBERT ELMAN *Arch Surg*, 1948, 57 185

The value of parenteral protein feeding depends (1) on the importance of protein feeding itself, and (2) on the availability of adequate methods. The old idea that protein is available from the large dispensable body stores has been discarded. A basic principle in the treatment of disease is that all deficits should be avoided.

There are two general conditions in which the parenteral administration of protein is indicated. When there is a deficit of hemoglobin and plasma they are administered intravenously in the form of whole blood. The second condition, that of a deficit of protein food, presents a different problem of parenteral administration. Protein food normally becomes available to the body in the form of amino acids or combinations thereof.

For parenteral administration it is necessary to have a protein containing the minimum amount of essential amino acids. A second requirement is that the mixture provoke no serious consequences when injected either subcutaneously or intravenously. Solutions of hydrolyzed protein which we use at present must be mixtures of only pure amino acids.

Studies of the efficacy of protein food are discussed or suggested by the author under six categories as follows:

- 1 The maintenance of nitrogen balances
- 2 The effect on regeneration of plasma protein
- 3 The demonstration of tissue protein synthesis
- 4 The ability to promote normal growth in rats
- 5 The ability to promote normal weight gain in adult animals
- 6 Analysis of the protein for essential amino acid content

The author discusses the clinical observations which give evidence of the benefit of parenteral administration of protein to surgical patients. The author suggested that parenteral administration will control the patient's feeling of hunger. The use of parenteral administration in a special group of cases, patients with intestinal fistulas, is recommended. The theory of protein metabolism which maintains that plasma proteins are actually a medium of exchange between foods and body proteins is also discussed.

For the immediate nutrition of tissues, amino acids should be introduced in amounts of 100 gm. or more a day plus the same amount of dextrose, together with some salt and vitamins. Whole blood should be given in addition, largely to restore the red cell mass to normal. Plasma transfusions will be of value to increase the level of plasma protein. The salt content of plasma is a disadvantage, but it has been

eliminated by the newer preparation of salt-poor albumin which has proved to be more valuable.

The Effect of Caronamide with Heparin on the Coagulation of Human Blood HOWARD D. SIRAK, ROBERT S. MCCLEERY, and CURTIS P. ARTZ *Surgery*, 1948, 24 811

Caronamide has been used to prolong and augment the blood level of penicillin. When given orally, caronamide inhibits the tubular excretion of penicillin as well as paraminobenzoic acid, diodrast, and other compounds totally unrelated structurally to caronamide. Since heparin levels, like penicillin levels, are hard to sustain, it was believed that the effect of caronamide with heparin might be similar to that of caronamide with penicillin, making it more effective and less expensive to administer.

Ten patients were studied and the effect of caronamide with heparin was determined by performing heparin tolerance tests on successive days before and after the administration of caronamide.

The results were studied by determining the maximum response, the intermediate response, the minimal response, and the group averages in all patients. Heparin levels and prothrombin determinations were recorded and the time relationship of the administration of the two drugs was investigated.

The authors demonstrated that caronamide administered as a single 4 gm. dose, or as a course of multiple doses, markedly increased the effect of heparin on the coagulation time of human blood. Intravenous heparin in saline solution, given one-half hour after a single dose of caronamide, caused a progressive enhancement of the effect of an equal dose of heparin administered on each successive day.

In 8 of the 10 patients studied, this enhancement reached a peak in approximately 3 days and was manifested by a two to tenfold increase in response of the coagulation time to heparin. The peak was followed by gradual return to a normal response 2 to 3 days later.

Incomplete evidence suggested that the effect obtained in these cases was probably due to the formation of a new compound and not to a caronamide blockage of the renal excretion of heparin.

The fact that the enhancement of small doses of heparin can be achieved with the use of caronamide makes the outlook very promising for a reduction in the cost of heparin therapy.

JOHN E. KARABIN, M.D.

Carcinogenic and Anticarcinogenic Substances E. C. DODDS *Lancet*, Lond., 1948, 2 837

The production of chimney-sweep squamous epithelioma, mule spinner carcinoma, cancer of the mouth, and other forms of carcinoma was long supposed to be a very slow process attributable to gen-

eral nonspecific chronic irritation acting over a long period. Subsequently it was proved that there was something extremely specific about the irritating action of soot. Commencing in 1921, Kennaway and his coworkers demonstrated that carcinogenic substances could be formed from materials containing only carbon and hydrogen, which led to the synthesis and isolation, from tar, of carcinogenic polycyclic hydrocarbons. Biological investigation revealed big differences in the quantitative activities of various compounds. The author points out objections to the concept that long-term irritation is necessary for the production of cancer.

Thus, in cancer of the penis the carcinogenic potentiality is conferred during the first few years of life and in spite of subsequent circumcision, malignancy occurs several decades later. Certain forms of industrial cancer similarly develop long after comparatively short exposure, e.g., cancer of the respiratory passages from exposure to dust in the carbonyl process, carcinoma of the bladder from B-naphthylamine and benzidine used in dye processing, pulmonary neoplasia similar to sarcoidosis as a result of beryllium dust.

Evidence points to the fact that the body itself can produce substances (estrogens) which change tissues to such an extent that they may later develop into carcinomas. Possibly other factors are involved in this malignant transformation.

Efforts to render the organism insensitive to carcinogens have generally proved to be disappointing. Only one method of protecting sensitive animals from the carcinogenic action of polycyclic hydrocarbons on the skin has been found and this immunity is only temporary (mustard gas). Extensive studies on a heterogeneous collection of supposedly anticarcinogenic substances have shown that some possibly exert slight beneficial effects. It appears probable that this is the consequence of a nonspecific action on the general health of the animal rather than a specific action on the growth itself. Several studies emphasize the fact that diet may play some part in malignancy.

Opinion is divided as to the influence on cancer of the folic-acid group of substances (diophterin and, particularly, terophterin). However, interest appears to have largely evaporated. A group of compounds, known as antifolic acid substances, has also been intensively investigated since these compounds seem

capable of damaging malignant cells. Promising results appear to have been obtained clinically with one of these agents, A-methopterin.

Coley's fluid has not given uniform results and therefore its administration has been generally discontinued. Stilbestrol, by its action on the anterior lobe of the pituitary gland, effects a kind of biochemical castration and thereby controls the local and secondary growths of prostatic cancer for a prolonged period. This was the first highly successful attempt with chemotherapy in the control of cancerous conditions.

The author points out that androgens are not entirely foreign to the female and therefore their empirical employment is unwarrantable. Opinion is reserved as to the effectiveness of testosterone propionate in mammary or genital tract carcinoma in women. The palliative use of nitrogen mustard has proved, on occasions, to have some beneficial effects at first. Urethane has similarly been administered for its palliative action on blood forming organs.

Thus, while there are a great many ways of producing cancer, with no fundamental connection between them, once the process commences we have no means of stopping or checking it by direct action. All the anticarcinogenic substances and agents act indirectly.

DAVID H. LYNN, M.D.

EXPERIMENTAL SURGERY

Studies in Cellular Growth. MAYWELL MALTZ. *Brit J. Plast. Surg.*, 1948, 1: 187.

Anti-mouse and human granulation tissue serums were prepared by injecting rabbits with antigens prepared from these two tissues. Wounded mice injected with small amounts of these sera showed accelerated healing. Larger amounts of the serum derived from mice retarded healing, whereas larger amounts of the serum derived from human granulation tissue had no retarding effect. Small doses of the serum from mouse granulation tissue plus small doses of an antisplenic serum stimulated cellular growth of sarcoma 180 in mice. A stimulating dose of the antisplenic serum plus a larger dose of the anti-mouse granulation tissue serum retarded and destroyed growth of this sarcoma.

This same combination retarded and destroyed spontaneous breast carcinomas in mice.

an approach to the ideal

Davis & Geck pioneered the development of the Atraumatic needle principle to meet virtually every situation where minimum trauma is essential. In design and construction, D&G Sutures with Atraumatic Needles approach the ideal more closely than any other combination for these reasons

- 1 Needles and sutures are practically the same diameter and form a smooth, continuous unit.
- 2 The method of affixing insures positive anchorage to the suture—it cannot pull out and its strength is unimpaired at the contact point.
- 3 Construction of swaged-on portion provides a sleeve of exceptional strength which will not bend or break and has no projecting edges
- 4 All curved needles have a flattened area to prevent turning in the needle holder
- 5 Each Atraumatic suture-needle combination has been developed in collaboration with recognized authorities and represents the consensus of professional opinion in its particular field

THE D&G ATRAUMATIC SUTURE-NEEDLE LINE is the most comprehensive line of its type available.

THE SURGICAL CORRECTION OF CONSTRUCTIVE PERICARDITIS

EMILE HOLMAN, M D, F A C S, and FORREST WILLETT, M D, San Francisco, California

THE operation for chronic constrictive pericarditis, whose ill effects stem from the concomitant compression of the heart and its large vessels either by contracting scar or by the pressure of fluid confined within a rigid-walled envelope, has yielded varying results, some disappointing and some spectacularly brilliant. Twenty-two deaths on the operating table in 265 reported cases (Table I) provide abundant proof of the hazardous nature of the operation and 48 early postoperative deaths further testify to the extreme gravity of the disease. All the more gratifying, therefore, are the 118 cases reported as restored to normal health, and the 44 cases reported as improved.

The following important factors contributed to the success of the operation: its application in young individuals in whom other organs were normal and in whom liberation of the compressed heart was the only correction necessary, the availability of intratracheal anesthesia, and such adjuncts in after-care as oxygen, transfusions, and antibiotics, an adequate exposure of the heart which permitted ready access to critical areas for the removal of the offending scar, and the courage and technical skill of the operating surgeon which enabled him to pursue the operation until

adequate decompression of all critical areas had been achieved.

Factors contributing to poor results were such considerations as the etiology of the primary pericarditis, whether tuberculous or pyogenic in origin, the former being strikingly dangerous in the advanced chronic stage, the selection for operation of exceedingly ill patients whose only hope lay in liberating the hampered heart but who died on the operating table or within a few hours after operation, technical difficulties leading to lacerations in the thin walled auricle or in the myocardium of the right ventricle with fatal hemorrhage, inability to remove the scar because of penetration of cardiac musculature by calcium deposits, inadequate removal of scar necessitating secondary operations, failure to remove the scar over critical areas such as the inferior and superior vena cava, technical difficulties imposed by the type of operative exposure of the heart, and lastly the postponement of a correct diagnosis until changes had occurred in the cardiac musculature so that liberation of the compressed heart resulted in overdistention of attenuated and atrophied myocardium and in circulatory failure.

Considerable difference of opinion has been expressed by various writers as to what really are critical areas. Schmieden (30, 31), whose excellent articles stimulated internists to diagnose and surgeons to operate upon this theretofore rarely recognized entity, states

From the Veterans Administration Hospital Fort Miley and the Stanford University Medical School.

Presented in the Symposium on Surgery of the Heart and Great Vessels before the Clinical Congress of the American College of Surgeons, Los Angeles, California, October 18-22, 1948.

*Cases included in the survey of Heuer and Stewart (19)

**The same patients

"The operative technique is based upon the following fundamental principles (1) liberation of the left ventricle first, in order that it can receive and immediately deliver to the systemic circulation the increased output of the right ventricle following its subsequent decortication and thus avoid the right-sided venous congestion that would otherwise occur, (2) freeing of the right ventricle, which then usually dilates more efficaciously and beats stronger. Owing to the thin wall of the auricles, these should not be freed. In order to avoid the development of deficiency of the auriculoventricular valves, thus leading to the immediate occurrence of an inflow venous congestion, the *decortication should never be performed beyond the coronary sulcus*.

"Special attention must be given the apex of the heart which is usually firmly fixed and considerable difficulty is encountered in the attempts to liberate it. If decortication of the apex of the heart, which is bound down to the diaphragm, should not be successful, normal systolic contraction is impossible, because during inspiratory depression of the left dome of the diaphragm the heart is elongated and during systole becomes lancet shaped. In order to remedy this undesirable condition left-sided phrenicotomy is generally recommended, since this results in sufficient relief."

Graham in his book, "*Surgical Diseases of the Chest*" quotes Schmieden at length, and adds "It is not infrequently necessary to perform a Talma operation, since the operation of cardiolysis may take care of everything but ascites." A patient is presented in whom decortication failed to influence the ascites, and for whom a Talma operation was being considered when he died.

Churchill, who in 1928 operated successfully upon the first case in America, states

"If the scar extends laterally over the left ventricle this region should be removed as the first step. Excision may be carried as far as the phrenic nerve, but I have in no instance sacrificed this structure.

"The sulcus formed by the descending branch of the left coronary artery is apt to be the site of densely adherent scar, and this region should be approached with caution to insure the preservation of this important vessel. In one instance a thickened calcified band 2 millimeters in diameter marked this sulcus. A maneuver that has been advantageous in several instances has been to establish a new plane of cleavage over the right ventricle so that the interventricular groove may be approached from both sides.

"A second very adherent region is the right auriculoventricular groove, in intimate association with the diaphragmatic pericardium. In many cases of the disease the mobilization of the auriculoventricular groove has been a crucial step in relieving the obstruction to right ventricular filling. Keith has shown that the free motion of the auriculoventricular groove is an important physiologic mechanism in the action of the right heart. Every effort, therefore, should be made to free this area if it can be done with safety, and once past it, the inferior cava can usually be readily exposed. Actual decortication of the auricle is a hazardous procedure owing to the thin wall of this chamber of the heart. It has been attempted in only 3 instances.

"Dissection of the diaphragmatic pericardium and scar from the heart should be as complete as possible but in no instance has it been carried to the left auricle.

"When an area of encapsulated fluid exists it is important to resect the wall of the cavity that is in contact with the surface of the heart. The removal

of the parietal pericardium over such an area can be accomplished simply, but will not have the desired effect. A new line of cleavage must be established and a true decortication of the heart carried out."

Heuer and Stewart (18), who present an enviable record of 18 cases without a post-operative death, state

"How much of the pericardium it is necessary to remove in order to achieve satisfactory results is a difficult question. We have removed as completely as possible the pericardium over the left and right ventricles, but have not attempted to remove the adherent pericardium over the auricles. An effort has been made to free the apex, and if possible the dissection is carried well down on the diaphragmatic portion of the pericardium. No attempt has been made to go beyond the right auriculoventricular groove, nor have we attempted to free the great vessels at the base."

Blalock and Burwell, whose review in 1941 is recommended for its excellent presentation of the pathologic, physiologic, clinical and surgical aspects of the disease, state

"Most are agreed that actual decortication of the auricles is a hazardous procedure due to their thin walls and should not be attempted. If the ventricles are properly freed of scar, the undecorticated auricles are able to conduct sufficient blood to the ventricles to supply the needs of the body. Several observers have commented on the need for the removal of the scar from the site at which the venae cavae enter the heart. It is our impression that *this is rarely necessary and even more rarely accomplished successfully*. Schmieden states that complete liberation of the left ventricle is the most important part of the procedure and that in most cases this is the only surgical measure that is necessary. We question seriously the correctness of this view. Most patients with constrictive pericarditis have remarkably little dyspnea and edema of the lungs in comparison with the marked evidence of congestion in the systemic circulation. Most of the signs and symptoms are attributable to back pressure from the right side of the heart. In our experience, major emphasis has been devoted to decorticating the right ventricle."

"An interesting unanswered question is concerned with the reason for the very slow improvement that occurs in many patients following pericardiectomy. The prevailing opinion is that the constriction has resulted in atrophy of the heart muscle and that a considerable time is required for a return to the normal condition. This explanation does not suffice in all instances. At any rate, *one should not despair if the improvement is slow and if a period of many months is required for the desired decline in the venous pressure and the elevation in the cardiac output*."

Harrington, in his report of 24 personally observed cases, states

"I believe it is advisable to separate as much of the pericardial scar as possible from the ventricles, the right auricle and orifice of the inferior vena cava, and it is of particular importance to separate the attachment of the right ventricle to the diaphragm. It is of equal importance to separate the apex of the heart and I believe that this should be done early in the operation if possible. Separation of the heart muscle from its fixed attachments to the diaphragm is one of the most important considerations in re-establishing the action of the heart."

Beck, in discussing Harrington's article, states

"The compression scar must be removed whenever it exists. Ventricles, auricles, venae cavae must be relieved of any compression in order to obtain a cure. Partial operations yield partial results and increase the probability of recurrence of scar."

Sellors, who presented in 1946 the latest review of the subject in the English literature, states

"Excision should aim primarily and possibly only at freeing the ventricles, though for anatomical reasons even this is rarely achieved. The very thinness of the auricles and the great veins makes interference over them a hazardous undertaking. *At no time is it wise to carry dissection beyond the range of vision or unimpeded access*. The obliquely placed auriculoventricular groove marks the upper limit, and though clearance beyond this area is frequently advocated it can be seen from a section of this region that there is little margin for error. *It is highly doubtful that the constriction around the caval and auricular regions could ever produce such a degree of stenosis that a direct surgical attack on this region should be necessary*."

"A lowering of the venous pressure and reduction of ascites and liver size may be noted within a few weeks, but full and final improvement should not be expected within 12 to 18 months. The venous pressure often persists at a high level without causing the patient much inconvenience."

Decker, writing in 1947, argues that only the left ventricle requires decortication and that only a limited amount of pericardium should be removed as it is not an unnecessary organ!

The marked diversity of opinion expressed by these writers as to the extent of necessary decortication arrests one's attention. Striking also is their resigned acceptance of a long delay in securing improvement and reduction in

venous pressure following a presumed adequate pericardiectomy

The purpose of this paper is to emphasize two all important principles in the operation for constrictive pericarditis first, the necessity of exposing adequately the entire heart and its great vessels, so that the surgeon may have ready access to every strategic area requiring liberation, and, second, the imperative need of a wide removal of the diseased pericardium, not only that overlying the easily accessible anterior surface of the heart, but also that lying beyond or around each border of the heart, including most particularly the decortication of the right and inferior borders, and of the superior and inferior vena cava

As to the operative approach for exposure of the heart, most of the above authors have employed the left parasternal incision with excision of segments of the third, fourth, fifth, and sixth ribs and removal of the left half of the sternum. One of the serious limitations of this approach is revealed in the following comment by Churchill

"For a time during the freeing of the adhesions about the vena cava, adequate exposure necessitated pressing on the right side of the heart with the flat surface of the hand. This distinctly interfered with the filling of the heart, and the anesthetist reported that the blood pressure could not be obtained"

Decker, in common with a few others, prefers the intrapleural approach through the left sixth interspace

Both the left parasternal and the left transpleural incisions provide an unsatisfactory exposure of the right cardiac border, the liberation of which we believe to be the most essential part of the operation. Beck (3) realizing their inadequacy, has employed a bilateral approach through an H incision, but the intact midsternum limits greatly the necessary efforts of the surgeon. We should like to emphasize that the median sternotomy, from xiphisternum to second interspace provides an adequate and satisfactory approach. Some authors have recognized its value (Lilienthal, Roberts and Wilson), others state that its use is unnecessary, but we believe its merits will be increasingly appreciated. Having employed the usual left-sided parasternal approach in 2 patients, in which the right side

was liberated with great difficulty, we then employed the median sternotomy in the next 7 patients, with extraordinary improvement in the ease and effectiveness with which the necessary decortication could be done

As evidence that a more liberal decortication is necessary if delay in improvement or the persistence of a high venous pressure are to be avoided, we may cite the cases of secondary operations reported by several authors. Schmieden (30) recounts an instance in which he resected a "funfmarkgrosses" fragment of pericardium (about 5 by 5 centimeters) which failed to correct the ascites and edema until a greater resection was performed

In 2 of their 18 patients Heuer and Stewart (18) found it necessary to perform a second operation to free a greater part of the right heart. In 1 patient the second pericardiectomy was performed 5 years after the first operation, and in a second patient 8 years after the first operation. These authors also present some significant observations with reference to delayed improvement in their remaining patients

"In 7 patients improvement was evident at once or before the expiration of a month, improvement in 2 did not become pronounced until after the lapse of 2 or 3 months, in 5 not until after 6 to 10 months, and in 1 not until after 1 year. In 2, improvement was gradual, and in 3 improvement failed to occur. We have learned not to be discouraged if improvement after operation is not evident at once or rapidly"

Neuhof's experiences in 2 cases as presented by Friedberg and Hitzig are equally instructive. In Case 1 at the first operation in January, 1936, "a large portion of the pericardium overlying the right ventricle was removed," which, however, failed to correct the ascites, the pleural effusion, and the elevated venous pressure. In June, 1936, at a second operation the heart was approached through a left transpleural incision and a 7.5 by 5.5 centimeter fragment of pericardium was removed from over the left ventricle. Venous pressure remained elevated for 6 months but by December, 1936, it had dropped to 4 centimeters and the patient was well. In a second patient with ascites of a year's duration in whom a block of the inferior vena cava was postulated, the right side of the heart was

Fig 1 Drawing from autopsy observation showing normal appearance of superior and inferior vena cava, indicating that both lie within the pericardium for 1 to 2 centimeters before entering the right auricle and are therefore subject to compression either by intrapericardial fluid or by contracture of pericardial scar or by the late calcium deposits in pericardial effusions

freed through a right-sided approach at the first operation, which failed to correct the pleural effusion and the ascites. At the second operation 6 months later through a left transpleural approach, the pericardium over the left ventricle was excised. After this operation the ascites persisted temporarily, requiring 1 paracentesis, followed by complete recovery.

Harrison and White report 2 instances from Churchill's clinic in which reoperation was necessary. In 1 patient, ascites persisted for 2 years after the first operation but disappeared completely after a second pericardiectomy. In the second case, despite 2 pericardiectomies 14 months apart, and an omentopexy 4 months after the second decortication, the ascites was not corrected. At autopsy 6 years after the omentopexy it was seen that an area of the lower anterior portion of the pericardium measuring only 6 by 5 centimeters

had been removed. There still remained over the left anterolateral aspect a calcified plaque 9 by 6 centimeters and over the anterolateral aspect of the right ventricle an area of pericardial calcification measuring 9 by 4 centimeters.

It may be categorically stated first, that a limited or incomplete removal of constricting scar may result in failure or long delay in the correction of ascites, and second, that when ascites does persist, not a Talma operation, but the removal of more scar is indicated. Failure to lower a high venous pressure may follow inadequate removal of scar overlying one of several areas: the right ventricle or auricle, the superior or inferior vena cava, or even the pulmonary artery at the base of the heart. Indeed, the pericardium over the left ventricle has not in any of our cases been as greatly thickened nor as "oppressive" as has

Fig 2 Constriction of inferior vena cava in a dog to $\frac{1}{2}$ its normal diameter produced a rise in venous pressure in the leg and a marked ascites noticeable on the 7th day. Note that the ascitic fluid reached a pressure as high as 20 centimeters of water, and that removal of the fluid reduced the venous pressure in the leg from 34 centimeters to 15 centimeters of water. A venous pressure of about 15 centimeters of water in the leg seemed to be the critical level at which ascites would develop.

the pericardium over the right heart and the 2 caval vessels. An explanation for this may lie in the greater and more forceful pulsating action of the left ventricle which forces the irritating pericardial fluid of the precontractive period into the less active and more quiet areas with consequently greater inflammatory excitation of the overlying pericardium. If the strongly pulsating, highly muscular left ventricle can be hampered visibly in its activity by a constricting pericardium as seen at fluoroscopy, how much more vulnerable to such constriction would be the easily compressible superior and inferior venae cavae as they lie in the intrapericardial space (Fig 1). The effects of such compression have been studied in our experimental laboratory. Constriction of the inferior vena cava to one-half its normal caliber in a 14 kilogram dog produced a permanent ascites in approximately 7 days (Fig 2). Constriction of the pulmonary artery to approximately one-half its normal caliber led to the development of an ascites in about 7 days (12). Constriction of the superior vena cava alone above the azygos vein produced no trouble, but when constricted below the entrance of the azygos vein, a pleural effusion occurred on about the ninth day (13). This last observation suggests that the pleural effusions so commonly observed in the presence of constrictive pericarditis may not be

due necessarily to compression of the left heart but to superior vena caval constriction. Even more imperative, therefore, is the need of decorticating the superior vena cava.

The thickened pericardium lying between the inferior border of the heart and the diaphragm is also a critical structure requiring excision. Probably as the result of gravity, the irritating pericardial fluid, which precedes the scarring, is directed to the bottom of the pericardial sac, thus subjecting the diaphragmatic pericardium to the greatest inflammation, and therefore, to the greatest thickening and greatest subsequent contraction. This thickened pericardial sheet anchors the heart rigidly to the diaphragm, so that as the latter descends in inspiration, the heart is hampered even further by traction resulting in limitation of its filling and of its contraction. It is this increased restriction of cardiac filling and contraction during inspiration to which may be ascribed the momentary disappearance of the pulse, the so called paradoxical pulse, that invariably accompanies constrictive pericarditis.

The calcified and thickened pericardium on the posterior aspect of the heart cannot and need not be removed, but it is important to recognize that fibrous tissue will continue to contract, that the removal only of the easily accessible anterior pericardium is quite inadequate, and that a satisfactory pericardiectomy must include also excision of the constricting envelope beyond the left cardiac border, beyond the right cardiac border, and beyond the inferior cardiac border. This beyond the border decortication is necessary in order that the scar that remains may not in contracting further, enclose the heart in its grip.

Our observations indicate also that there is considerable variation in the thickening of the pericardium, and therefore in the effects of its constriction, depending upon the part of the heart or great vessels involved. In Case 2 the patient had been troubled with ascites for 6 years which then spontaneously disappeared. There followed a puffiness of the entire face and head (Fig 3) due to peripheral edema which fluctuated with chemically induced diuresis. At operation, following decortication

Fig 7 (Case 4) Diagrammatic presentation of operative findings showing marked thickening of entire pericardium without calcification, with particular thickening of the pericardium between the heart and the diaphragm, compressing the inferior vena cava and producing ascites, which disappeared promptly following pericardiectomy

Fig 8 (Case 5) Diagrammatic sketch of operative findings showing thickened pericardium, particularly across the base of the heart. A pocket of intrapericardial tuberculous pus lay over the anterior heart surface. Stippling shows areas of calcification which penetrated the cardiac musculature

It may be true, as Blalock and Burwell contend, that compression of the right heart is usually responsible for most symptoms, but we would add that constriction of the vena cava may continue to be a disappointing source of trouble if only the right heart is

decorticated and actual liberation of the venae cavae is disregarded

That late improvement may occur even after a limited pericardiectomy is patent. A possible explanation is that the heart through more vigorous pulsation may slowly extrude

Fig 9 Marked reduction in venous pressures as determined before and after operation. Note preoperative differences in pressure in arm and leg in last 3 cases, probably explicable on basis of an associated ascites

Fig 5 (Case 3) a, Marked ascites, bilateral varicocele, and bilateral varicose veins in presence of constrictive pericarditis b, Prompt improvement within 3 weeks after operation performed on July 7, 1947, which disclosed a marked constriction of the inferior vena cava c, d, Complete cure October 24, 1947

Fig 6 (Case 3) Diagrammatic sketch of operative findings showing very mildly thickened pericardium over the left heart, marked thickening and calcification over the right heart and inferior vena cava, and along the inferior cardiac border fixing the heart rigidly to the diaphragm

sure of arm and leg were recorded before operation. These differences were undoubtedly related to the associated ascites, the result probably of inferior vena cava compression. A somewhat high residual venous pressure in Case 5 is attributed to our inability to remove calcified tuberculous scar penetrating the cardiac musculature. In some instances the long delay but ultimate lowering of venous pressure in the arm may conceivably be due to impeded flow of blood through the superior vena cava resulting from its incomplete decortication. If by chance the inferior vena cava in such a patient had been adequately liberated, the unimpeded flow of blood through it would, during succeeding months, encourage the development of a collateral venous bed by way of this unconstricted vessel which would be accompanied *pari passu* by a reduction of the venous pressure present in the arm.

Fig 11 The 2 halves of sternum are separated by self retaining rib spreader applied after freeing mediastinal areolar tissue and right and left pleurae from undersurface of sternum and rib cage

Fig 12 Pleura and lung are dissected free from anterolateral pericardium on both sides to permit excision of thickened pericardium as far, approximately, as the phrenic nerve, which however is not easily or always identifiable

regenerated and the patient remains perfectly well. In Case 4 roentgenograms taken since the median sternotomy was performed show a marked shift of the heart when the patient's position is changed from one side to the other indicating that it has not become rigidly fixed to the undersurface of the replaced sternum.

Because of the large area of denuded and traumatized tissue produced by pericardiectomy, sometimes performed in the presence of active tuberculous granulation tissue, there may be a considerable outpouring of wound fluid necessitating drainage of the operative site. This drainage has been effected by deliberately incising the right pleura along its mediastinal border where it has not already been opened and providing for removal of the fluid from the right chest either by repeated aspirations (Case 3) or by intercostal tube drainage (Cases 4 and 5). In the 3 cases in which median sternotomy was used, complete primary healing of the operative wound has occurred—even in the presence of an active tuberculous pericarditis as in Cases 4 and 5.

That such drainage from the large operative area is necessary is evident from our experiences. In Case 3 following operation on July 5, the right chest was aspirated 4 times in the period from July 7 to August 14 for a total of 1970 cubic centimeters of bloody fluid. In Case 4 only 100 cubic centimeters of serosanguineous fluid escaped from the intercostal catheter in the first 24 hours, and none thereafter, but on the second postoperative day 280 cubic centimeters of reddish fluid was aspirated from the right chest and none thereafter. In Case 5, 1,100 cubic centimeters of serosanguineous fluid escaped from the intercostal drainage tube in the first 24 hours, 400 cubic centimeters in the second 24 hours, and none thereafter. Several aspirations were performed subsequently with gradual reduction in the amount of fluid removed. Most writers do not advocate drainage of the wound, but it is instructive to note that in 15 of Heuer's 18 cases, none of which was drained, an accumulation of fluid occurred in the chest, for which aspiration was found necessary in 7 cases.

Fig 10 Steps in pericardiectomy. *a*, Incision in skin is excentrically placed to avoid its lying directly over vertical incision, *b*, through midsternum. Xiphisternum is excised. Sternum is divided horizontally in 2d interspace.

itself from its investing pericardium, or that gradual and slow recession of the scar left around the heart results in decompressing critical areas.

Profiting by the experiences and suggestions of the surgeons quoted earlier in this paper (3, 5, 6, 8, 11, 14, 15, 18, 19, 20, 24, 28, 31, 32) and by our own observations in 9 clinical cases, confirmed by experiences in the experimental laboratory, the following plan of operative procedure is presented (Figs 10 to 18)

TECHNIQUE

A median sternotomy is performed, with excision of the xiphisternum and horizontal division of the sternum in the second interspace. The use of the power saw in dividing the sternum or of the powerful long-handled Bensen bone-cutting forceps is to be preferred to the Lebsche "sternal knife" or chisel which necessitates pounding upon the chisel and indirectly upon the bone with a mallet. The latter technique must be condemned for its shocking effect upon an already seriously ill patient. It was noted in the old days of operations for now almost extinct chronic osteomyelitis that the hammer and chisel were lethal weapons to be avoided by surgeons in very ill patients.

The objection that in median sternotomy both thoracic cavities may be entered is no longer valid since intratracheal anesthesia is usually employed. A rent into the left pleural cavity can usually be avoided or can be closed successfully, but it is almost inevitable that the right thoracic cavity be entered if adequate liberation of the vena cava is to be achieved. Following careful displacement of the pleura lateralward on both sides, the pericardium is incised over the area of the left ventricle, and is cautiously mobilized beyond the left border of the heart as far laterally as the left phrenic nerve if it can be identified but which should not be injured, the pericardium over the right ventricle is then mobilized anteriorly, with excision of the pericardium overlying the pulmonary artery, the ascending aorta, and the superior vena cava. The right border of the heart is freed so as to yield a good view of the superior and inferior venae cavae. Inferiorly, the heavy, frequently calcified pericardium lying between the inferior border of the heart and the diaphragm is then excised from the inferior vena cava on the right border to the apex of the left ventricle on the left border. In this excision normal bundles of the diaphragm should be exposed.

The right auricle must be liberated with caution if direct removal of the overlying pericardium is attempted. That its removal is possible was proved by our experiences, but if this seems too hazardous, the pericardium may be incised, both along the auriculoventricular groove, and at the base of the heart leaving the intervening pericardium attached to the auricle. This maneuver has the effect of liberation and should permit the desired expansion of the auricle.

The closure of the median sternotomy is easily effected by the use of 2 or 3 No. 1 stainless steel sutures applied not to cartilage but to the bony part of the sternum, a precaution designed to avert infection in such poorly vascularized tissue as cartilage.

We consider removal of the thoracic wall overlying the heart as unnecessary. In constrictive pericarditis the heart is limited not by the bony thorax but by the pericardium. In Case 2 the sternum and ribs have completely

Fig 11 The 2 halves of sternum are separated by self retaining rib spreader applied after freeing mediastinal areolar tissue and right and left pleurae from undersurface of sternum and rib cage

Fig 12 Pleura and lung are dissected free from anterolateral pericardium on both sides to permit excision of thickened pericardium as far, approximately, as the phrenic nerve, which however is not easily or always identifiable

regenerated and the patient remains perfectly well. In Case 4 roentgenograms taken since the median sternotomy was performed show a marked shift of the heart when the patient's position is changed from one side to the other indicating that it has not become rigidly fixed to the undersurface of the replaced sternum.

Because of the large area of denuded and traumatized tissue produced by pericardiectomy, sometimes performed in the presence of active tuberculous granulation tissue, there may be a considerable outpouring of wound fluid necessitating drainage of the operative site. This drainage has been effected by deliberately incising the right pleura along its mediastinal border where it has not already been opened and providing for removal of the fluid from the right chest either by repeated aspirations (Case 3) or by intercostal tube drainage (Cases 4 and 5). In the 3 cases in which median sternotomy was used, complete primary healing of the operative wound has occurred—even in the presence of an active tuberculous pericarditis as in Cases 4 and 5.

That such drainage from the large operative area is necessary is evident from our experiences. In Case 3 following operation on July 5, the right chest was aspirated 4 times in the period from July 7 to August 14 for a total of 1970 cubic centimeters of bloody fluid. In Case 4 only 100 cubic centimeters of serosanguineous fluid escaped from the intercostal catheter in the first 24 hours, and none thereafter, but on the second postoperative day 280 cubic centimeters of reddish fluid was aspirated from the right chest and none thereafter. In Case 5, 1,100 cubic centimeters of serosanguineous fluid escaped from the intercostal drainage tube in the first 24 hours, 400 cubic centimeters in the second 24 hours, and none thereafter. Several aspirations were performed subsequently with gradual reduction in the amount of fluid removed. Most writers do not advocate drainage of the wound, but it is instructive to note that in 15 of Heuer's 18 cases, none of which was drained, an accumulation of fluid occurred in the chest, for which aspiration was found necessary in 7 cases.

Fig 15

Fig 13 Incision is made in pericardium over the presumed site of the left ventricle and the left border and apex are dissected free first.

Fig 14 Anterior surface and base of heart are completely freed, if calcification permits, with excision of pericardium over pulmonary artery, aorta, and superior vena cava.

Fig 15 Right anterolateral border of heart is liberated by excision of pericardium overlying right auricle and inferior vena cava. Right pleural cavity is usually entered during this dissection. Right phrenic nerve should not be injured.

A useful tool in separating the heart from the pericardium is the so called "peanut" dissector, a small round pea-sized bit of gauze in a

curved clamp. By painstaking slow dissection, now blunt, now sharp, the proper cleavage plane can be maintained, but is easily lost

Fig 16

Fig 17

Fig 16 Decortication is completed by excision of pericardium, usually greatly thickened and calcified, lying between anteroinferior border of heart and the diaphragm. Normal muscle fibers of diaphragm may be brought to view during this dissection, which should run from inferior vena cava to apex of heart.

Fig 17 Sternum is reapproximated by 2 heavy steel wires placed in bony part of sternum—not in avascular cartilaginous part.

Fig 18 Fascia and deep subcutaneous tissue are reapproximated with interrupted silk or cotton sutures and skin is reapproximated with fine steel or silk sutures. Right pleural cavity may be deliberately connected with mediastinal space and drained by intercostal catheter in 5th or 6th interspace in nipple line.

Fig 18

if speed is the watchword rather than safety. Bigger's suggestion to retain the pericardium back of the advancing edge of dissection be-

tween pericardium and myocardium may be lifesaving in case the myocardium wall is accidentally perforated, or excessive bleeding is

MARTIN

Fig 19 Case 4 October 20, electrocardiogram in the presence of a pericardial effusion showed low voltage in the QRS complex, and inverted T_1 and T_4 and flat T_2 and T_3 October 30, normal electrocardiogram with increased QRS voltage, and upright T waves accompanied the subsidence of effusion and reduction in cardiac shadow January 6 to April 9, the development of cardiac constriction was accompanied by decreased QRS voltage and by inverted T waves August 17, pericardiectomy May 12 was followed by marked improvement in QRS voltage and by normal upright T waves in leads 1, 2, and 3

encountered Resuturing the liberated but still attached pericardium to the myocardial surface may be an effective control

Klose's suggestion that the pericardial defect be repaired with a fat or fascial transplant may be cast into the limbo of unnecessary refinements as may also Beck's early suggestion that these patients be operated upon in a negative pressure chamber to avoid the ill effects of pneumocardiac tamponade

Selection of the optimum time for operation may be difficult, and must be determined by conditions present in the individual case In the absence of fever, and in the presence of calcification, which in itself is evidence of a long standing chronic state, the detrimental effects of the disease are wholly mechanical in origin and the operation may be done at any time following a period of bed rest, during which the elimination of tissue fluids is promoted by a low sodium diet and by chemically induced diuresis Optimum nutrition with supplementary vitamins should be stressed and the thoracic and abdominal cavities should be emptied of their fluid as completely as possible by aspiration just before operation

When the signs of compression are accompanied also by signs of acute inflammation, the problem becomes twofold control of infection, and correction of the mechanical obstruction to the normal circulation of the blood The immediate treatment of the in-

fection obviously requires rest in bed, optimum nutrition including supplementary vitamins, the administration of penicillin and streptomycin on the assumption of tuberculosis since tuberculosis usually cannot be proved or disproved until operation, and the correction of anemia Improvement will be apparent from the reduction in fever, lowering of pulse rate and decreased sedimentation rate Operation may be delayed until such improvement is manifested, but should not be delayed long if the mechanical disturbances of compression are prominent, incapacitating, and progressive Under these conditions, the sooner the compression is corrected the better will be the ultimate results In Case 4 only 7 months elapsed from the onset of symptoms due to acute pericarditis with effusion to pericardiectomy for constricting pericardium, in Case 5, 10½ months elapsed In both cases tubercle bacilli were demonstrated on culture of pericardial fluid removed at operation

The administration of streptomycin decreases the hazard of operating in the presence of active tuberculous pericarditis, as these cases illustrate In Case 4, streptomycin was reserved for the immediate postoperative period, since this was considered the crucial period of recovery, and its administration was continued for 3 months after the operation

In Case 5, on the assumption of an active tuberculous pericarditis, streptomycin, 1 gram

daily, was administered from November 27, 1947, to March 23, 1948. Pericardiectomy was performed May 15, 1948, and streptomycin, 2 grams daily, was again administered from May 10 to July 6, and 1 gram daily from July 6 to August 10, 1948.

The problem of early diagnosis, and the recognition of the disease, have been greatly clarified in the writings of White, Levine, Beck (1, 2), Burwell, and others. As Levine states, "it is amongst patients who are regarded as having heart failure, but in whom the ordinary causes are lacking, i.e., hypertension, coronary sclerosis, valvular disease, hyperthyroidism, or who are thought to have cirrhosis of the liver, in whom constrictive pericarditis will be found." Moreover, it is more commonly found in younger patients, the average age of 100 reported cases being only 25 years.

Any young patient, therefore, who presents symptoms suggestive of myocardial failure, but who has ascites or pleural effusion or peripheral edema associated with heart sounds that are quiet or muffled, and unaccompanied by a murmur, whose cardiac borders move but little under fluoroscopy, whose arterial pressure is low and pulse pressure small, and whose venous pressure is above 15 centimeters of water in the arm and 5 centimeters to 10 centimeters higher in the leg, should be strongly suspected of having constrictive pericarditis, and should be surveyed again with this diagnosis in mind. Particularly suspect should be the patient who has Beck's triad of a "small, quiet heart, ascites, and increased venous pressure," associated with the corroborative evidence of an electrocardiogram exhibiting low voltage in the QRS complex and inversion of the T waves (Fig. 19).

SUMMARY

In 265 recorded operations for constrictive pericarditis, 22 deaths occurred on the operating table, 48 deaths occurred in the early post-operative period, 118 cases were considered cured and 44 cases improved.

The following important factors contributed to the success of the operation: its application in young individuals in whom other organs were normal and in whom liberation of the

compressed heart or its vessels was the only correction necessary, the availability of intratracheal anesthesia, and of oxygen, transfusions and antibiotics, an adequate exposure of the heart permitting ready access to critical areas for the removal of the offending scar, the courage and technical skill of the operating surgeon which enabled him to pursue the operation until adequate decompression of all critical areas had been achieved.

Factors contributing to poor results were such considerations as the etiology of the primary pericarditis, whether tuberculous or pyogenic, the selection for operation of exceedingly ill patients, technical difficulties such as tears in the thin-walled auricle or in the myocardium of the right ventricle, inability to remove the scar because of penetration of cardiac musculature by calcium deposits, failure to remove scar over critical areas such as the inferior and superior vena cava, technical difficulties imposed by inadequate exposure of the heart, and lastly, the postponement of a correct diagnosis until the liberation of attenuated and atrophied myocardium resulted only in circulatory failure.

A satisfactory and adequate pericardiectomy must include liberation of all borders of the heart, and of both venae cavae. The inferior cardiac border must be liberated by excision of the pericardium lying between the heart and the diaphragm.

Persistence of ascites following pericardiectomy is evidence of an inadequate decortication and demands reoperation and removal of more scar, rather than an omentopexy or Talma operation.

The best evidence of an adequate operation is prompt and permanent lowering of venous pressure.

To achieve the exposure necessary for an adequate inspection and decortication of the heart, a median sternotomy with transverse division of the sternum in the second interspace is recommended. Reapproximation is by several stainless steel sutures inserted through bone, not through avascular cartilage.

The wound should be drained, preferably into the right pleural space from which the fluid can be removed either by aspiration or by intercostal drainage.

In cases suspected of having tuberculosis or in which evidence of active inflammation is present, the preoperative preparation should include a prolonged period of bed rest with optimum nutrition, and the administration of penicillin and streptomycin. Operation should not, however, be deferred unduly, if the symptoms of compression are incapacitating, unaffected by therapy, and progressive.

Nine patients have been operated upon: 5 of unknown etiology, with 1 dead, 3 cured, 1 improved, and 4 of active tuberculous pericarditis, with 2 cured, 1 markedly improved, 1 improved.

BRONCHIECTASIS

A Study of the Segmental Distribution of the Pathologic Lesions

J R. MOORE, B A, M D, C M, S D KOBERNICK, B Sc, M D, C M, and
F W WIGLESWORTH, M D, Montreal, Quebec

WITHIN recent years, interest has been manifested in the possibility of resecting lung segments in bronchiectasis as opposed to performing lobectomies. The principles underlying the procedure of segmental lung resection are several.

The first and most important assumption is that bronchiectasis is not a progressive disease, or at least that the disease has progressed as far as it will by the time diagnosis is made (1), and thus that extension from one segment to another is not by spread of the bronchiectatic process from the affected segment but by involvement of the unaffected segment by an acute pulmonary infection. Such a view, of course, may be colored by an individual's underlying concept of the disease. It is an open question at the present time whether bronchial ectasia (from which the disease is named) is a primary phenomenon or merely secondary to parenchymatous disease. Certainly, it seems reasonable to suppose that an infected segment could, by overflow into another suitably situated segmental bronchus, produce infection of that segment (2). In reviewing his cases of segmental resection, Pilcher states, "It appears on review of these cases that in some the interval between bronchogram and operation has been too long, and there may have developed in the interval areas of disease which were not present before."

The second assumption is based on the consideration that bronchiectasis is primarily a segmental disease (1, 3, 7), even though it is very frequently multilobar (80 per cent in Churchill's series). We have seen no detailed pathologic study to confirm this, though in a general way, it appears to be correct, for example the lingular segment of the left

upper lobe is usually the only segment of this lobe involved.

The third consideration involved is the obvious advantage of preserving as much healthy lung tissue as possible for the patient's benefit, especially in bilateral and extensive disease. There is, of course, no criticism of this thought.

If these assumptions are correct, there should be no histopathologic changes present in segments which are normal bronchographically and grossly. Therefore, such segments may be saved for the patient's benefit.

With these points in mind, we thought it worthwhile to make a pathologic study of bronchiectatic lung tissue by examining each segment in detail. Only 7 cases have been studied over a 6 month period but it was thought that a report of even a limited study might emphasize the importance of detailed examination of the lungs in a problem which is still controversial.

The material consists of 7 cases of fairly early bronchiectasis in children, for which lobectomy, and in 1 case pneumonectomy, was performed by Dr Dudley E. Ross. As lingulectomy was the only form of segmental resection used, it was possible for us to study the gross and microscopic lesions in a number of segments, some of which were normal roentgenographically and some of which were diseased.

Examination of the lungs was carried out as soon as the specimens were brought from the operating room. They were dissected segmentally. The nomenclature is that used by Foster-Carter. Careful observations were made on the gross specimens, both before and after fixation of the specimen in 10 per cent formol saline. Depending on the size of the lung, one, two, or three sections were taken from each segment for histological examination. These were stained by modifications of Masson's trichrome technique, Weigert's stain

From the Departments of Pathology, Children's Memorial Hospital and McGill University, Montreal, Quebec.

GENERAL DESCRIPTION OF THE CASES

The patients, of whom 2 were males and the remainder females, varied in age from 2 to 11 years. The symptoms dated from 1 to 8 years prior to the operation. Further details are given in Table I.

Lipiodol installation was the most important diagnostic procedure used to determine the presence and distribution of bronchiectasis and was carried out in all cases (Table II). The roentgenographic distribution of the lesions is clearly indicated in Table II. The implications will be discussed later. Except in 2 instances (i.e. Case 5, in which pus was seen in the bronchus to the posterior basic segment and Case 4 in which all segments of the right side were involved) bronchoscopic examinations were not helpful in the localization of the disease according to segments.

GROSS APPEARANCE OF SPECIMENS

The lung parenchyma in all cases presented a uniform type of change. It was moderately collapsed and soft to doughy on palpation. Aeration was minimal and the cut surface was jelly-like to gelatinous as seen under the hand lens. No gross scarring was seen. There was no striking difference in the parenchyma between involved and uninvolved segments. In Case 4, the major bronchi were nodular

In Cases 1, 2, and 3 no bronchial ectasia; only questionable bronchial wall thickening were noted. Gross changes of the bronchi in the dorsal segment in Case 4 were present while in Case 7 there was slight ectasia without thickening. In the remainder of the cases no gross lesion was apparent in the dorsal segment bronchi. In Case 5 the lingular bronchi showed slight thickening of the wall while the basilar bronchi showed moderate changes of the same type. The lingular bronchi in Case 7 showed somewhat more marked changes than the basic segments. In Case 4 the middle lobe bronchi showed somewhat more marked gross changes than the basilar. The distribution of bronchial contents did not always correspond to the degree of ectasia. Except in Case 4, the bronchial contents were more mucoid than purulent and were relatively scanty.

HISTOPATHOLOGY

Before dealing in some detail with the lesions of the segments which on bronchographic and gross examination were uninvolved, a consideration of the overall picture in these cases will be made. The lesions were inflammatory in nature with the lymphocyte and monocyte as the predominant cells but a few neutrophils were present as well. The cellular infiltrate and fibrosis varied considerably from case to case and segment to segment. The bronchial wall

Fig 1 Photomicrograph of a normal bronchiole and adjoining alveoli of a 9½ year old child. For comparison with the other photomicrographs presented in this contribution. $\times 65$

Fig 2 Photomicrograph of dorsal segment bronchiole in Case 1. Small subepithelial granulation tissue mass in right upper area of bronchiole. Focal adventitial inflammatory infiltrate. Segment normal bronchographically. $\times 135$

matory lesions in our opinion became more and more marked as the bronchi became smaller. The major bronchi showed lesions which were not so severe as were those in the small bronchi and the bronchioles. Scarring also was more marked peripherally than centrally.

Lesions of the parenchyma (including respiratory or transitional bronchioles and alveoli) were common. The alveolar lesions were often focal and seemed to be related to

involved respiratory and terminal bronchioles, as well as to small bronchi. The lesions were those of inflammation with scarring. Probably alveolar fibrosis predominated over interstitial alveolar wall inflammation. Alveolar exudates were uncommon over a large area but occasional foci involving several alveolar lumens were found (except in Cases 1, 4 and 7). Traces of previous alveolar inflammation, as indicated by fibrous polyps occupying the lumens, were found in Cases 2, 3, and 5. Tiny subepithelial fibrous or granulation tissue masses were found projecting into the lumens.

Fig 3 Photomicrograph of respiratory bronchiole of left anterior middle segment in Case 3. Just above the center of the field is a tiny lymphatic surrounded by a collar of lymphocytes and neutrophils. A similar infiltrate is present in the alveolar wall in the lower right hand corner, as well as an area just above it. Bronchographically, there was no dilatation demonstrable in either of the lingular segments. $\times 125$

Fig 4 Photomicrograph of dorsal segment bronchiole in Case 2. There is moderate subepithelial fibrosis and muscle fibers at lower right hand corner of bronchiole. There is alveolar fibrosis below the bronchiole. Segment not filled bronchographically. $\times 50$

Fig 5 Photomicrograph of dorsal segment bronchiole in Case 3. Slight diffuse adventitial inflammatory infiltrate. At bottom of photograph, note the exudate lying in the tissues parallel to a small lymphatic vessel. Segment normal bronchographically. $\times 125$

Fig 7 Photomicrograph of small dorsal segment bronchus in Case 5. Moderate adventitial inflammatory infiltrate and fibrosis. At the bottom of photograph, note the irregular scar extending into the parenchyma. Segment normal bronchographically. $\times 65$

of the terminal and respiratory bronchioles in all cases. Partially collapsed alveoli were prominent.

Mucosal ulceration was rare and when present was focal in character. The epithelium was essentially normal with normal cilia in all cases, except Case 4, where a slight degree of focal metaplasia existed. Destruction of the elastic and muscle coats was far from striking, as can be seen from Table II, and was mainly focal in character. There was no correlation between ectasia, as demonstrated by bronchogram, and loss of these coats. In all instances, except those segments

showing marked inflammation, normal bronchi and bronchioles existed side by side with involved tubes. As the blocks were not serial sectioned, it is difficult to say whether such normal bronchi were uninvolved in their entire length. Focal and diffuse scars were found in some, either in the submucosa, the adventitia, or both.

Lymph follicle formation in the bronchial walls was not as marked a feature in most of these cases, as compared to the number present in well marked chronic bronchiectasis. Endarteritis obliterans of the pulmonary arteries was present only in those segments which

Fig 6 Photomicrograph of dorsal segment bronchus in Case 4. Marked inflammatory lesions with slight fibrosis. Quite marked ectasia is demonstrated bronchographically. $\times 65$

Fig 8 Photomicrograph of dorsal segment bronchiole in Case 6. This shows a slight inflammatory infiltrate of the submucosa and adventitia. Segment normal bronchographically. $\times 125$

Fig 9 Photomicrograph of small dorsal segment bronchus in Case 7. This segment showed very slight microscopic lesions, yet bronchographically there was moderate ectasia. Here there is seen a very slight peribronchiolar invasion by inflammatory cells. $\times 65$

Fig 10 Photomicrograph of small bronchus of mid basic segment in Case 1. Moderate inflammatory exudate of submucosa and adventitia similar in degree to the roentgenographically dilated anterior basic bronchi. Segment normal bronchographically. $\times 65$

were severely involved and was not a marked feature.

The lesions of the segments which were uninvolved on bronchographic and gross examination were on the whole similar in type but quantitatively less. These lesions are of the greatest interest in view of the inference in the surgical literature on segmental resection that bronchographically normal segments, found to be grossly normal at operation, can be safely left behind. Such seem to apply in the main to the dorsal segment of the lower

lobes as it is admitted that in nearly all cases the three basic segments and the lingular segments are usually involved. Churchill and Belsey do state, however, that commonly only the posteromedial (anterior middle branch in our terminology as far as could be determined) branch of the lingula is involved and it is a rare occurrence for both of the segments to be diseased.

In these 7 cases the microscopic involvement varied somewhat in different cases but in none of the supposedly normal segments were the lesions marked. In those noted as "very slight" in the table, the lesions were focal and were minimal in degree. They are perhaps colored by individual interpretation; nevertheless, we consider that such lesions are not present in normal lungs at this age. Those cases marked as "slight" in the table were minimal in degree but were fairly diffusely scattered throughout the segment and there is no doubt that these changes are abnormal.

The lesions were those of inflammation and its sequelae. The bronchial lesions consisted of thin infiltrations of lymphocytes with occasional neutrophils in the submucosa or adventitia. These tended to be focal rather than diffuse and were found in some bronchi but were absent in others. Small submucosal masses of granulation tissue or focal areas of scarring were sometimes found (Fig 2).

Fig 11 Photomicrograph of bronchiole in posterior basic segment in Case 1. Moderate inflammatory exudate involving whole thickness of wall with slight fibrosis. This was equal in degree to that of the anterior basic segment which alone was dilated bronchographically. $\times 65$

Fig 12 Photomicrograph of respiratory bronchiole of posterior basic segment in Case 1. Note infiltrate of the wall with extension into the contiguous alveolar walls. This lesion is a typical example of those found at this site in all bronchographically normal and diseased segments. Segment normal bronchographically. $\times 135$

Fig 13 Photomicrograph of respiratory bronchiole of left anterior middle segment in Case 3. Lymphoid collection present outside muscular coat of bronchiole. Inflammatory cells extending out along interstitial tissue (below and to right and left of bronchiole). Bronchography showed doubtful ectasia. $\times 138$

Lymphocytic infiltration of the adventitia or adventitial scarring was comparatively common. Nevertheless, the bronchial lesions were minimal in degree.

The bronchioles presented the relatively most marked lesions. The bronchioles were more widely involved by the chronic inflammatory infiltrates and the degree of infiltration appeared slightly more intense. Lymph follicle formation was present and was particularly striking in Case 1. We consider that the amount present was abnormal but have not laid stress on this finding. Submucosal fibrosis of slight to moderate degree was more common than in the bronchi. Thin collars of lymphocytes and neutrophils were present in scattered areas about tiny lymphatics (Fig 3). The alveolar walls contiguous to involved bronchioles showed variable changes, consisting of focal interstitial pneumonia or fibrosis with epithelization of the lumens. Occasionally one or several alveolar lumens contained a mixed exudate of macrophages and neutrophils. Alveolar expansion as a whole was poor and scattered foci of alveolar wall fibrosis were evident. Intra-alveolar fibrous polyps were occasionally found and in Case 5 they were relatively numerous.

It is useless to speculate on the origin and outcome of these lesions from the histopatho-

logic point of view. It is merely possible to state that definite, if minimal, inflammatory lesions were present.

DISCUSSION

From the clinical point of view, the roentgenologic diagnosis of bronchiectasis is the most reliable guide to the extent of the lesions. For all practical purposes, especially segmental surgery, it is the bronchographic appearance, coupled with examination by the surgeon at the time of operation, which determines the extent of the operative procedure. However, as Pilcher says, the exact value of palpation of the lung at operation has yet to be proved.

Bronchographic diagnosis of bronchiectasis was made in the segments as shown in Table II. The gross and microscopic findings are represented in parallel columns. It is evident that there are segments showing histopathologic inflammatory lesions in which no change was demonstrated by bronchography or by gross examination. The microscopic changes were similar in type to those seen in the segments which showed roentgenographic change but less in degree. The dorsal segments showed histopathologic involvement in every case, minimal in Cases 1, 6, and 7 (Figs 2, 4, 5, 6, 7, 8, and 9). In only 2 cases, Nos 4 and

7, was definite involvement demonstrated by bronchography. Case 7 was the converse of the others in that the lesions were minimal while the bronchographic examination showed moderate involvement. In 1 case, No. 2, the bronchus to the dorsal segment was not filled and here the microscopic changes were fairly marked with several minute healing abscesses. The difference between the lesions of the dorsal segments and those of the basic segments appeared to be quantitative only.

That extreme care must be exercised in the interpretation of the roentgenographic appearance in the selection of the segments for resection, is illustrated by the fact that even the more advanced lesions, on occasion, are not accompanied by changes in the roentgenographic appearance. In Case 1, only the bronchi to the anterior basic segment were abnormal, roentgenologically, whereas microscopic examination revealed lesions, as well marked as those of the anterior basic, in the bronchi to the other two basic segments (Figs 10, 11, and 12). Similarly, in Case 3, only the basic segment bronchi showed dilatation roentgenographically while the anterior middle and lateral middle segments of the lingula were definitely abnormal (Figs 3 and 13). It may be noted at this point that all the lingular segments were involved to an equal degree. In Case 6 the middle lobe bronchi were only slightly dilated bronchographically, while microscopically the lesions were severe.

It would appear from the foregoing that when disease is present to such a degree as to be visible roentgenographically, the adjacent segments are usually involved by inflammation, though to a lesser degree. It is possible nonetheless that these are early lesions, capable of progressing to either full blown bronchiectasis with permanent dilatation or to temporary dilatation of the reversible type (4, 6), and by the same token it seems equally reasonable to suppose that those inflammatory lesions may regress without the development of bronchial ectasia if the major focus of infection is removed. The relationship between duration of symptoms and the degree of this minimal involvement of segments unaffected grossly could not be determined in this group of cases.

From a purely histopathological viewpoint it is impossible to state whether the lesions were progressive or not. In the segments with very slight involvement, the possibility seemed remote but in the slightly involved segments one could speculate on the possibility of progression. If these lesions were secondary to extension from the involved segments, they might have cleared completely, following segmental resection. On the other hand, it is possible that they represent a persistent low grade inflammatory process following a pneumonitis.

In basic segments, however, where bronchography has not demonstrated dilatation, we have observed lesions as marked as those in segments in which involvement had been shown by roentgenographic examination. Therefore, we believe that extreme caution is necessary in evaluating the extent of the lesions. Correlation with bronchographic changes in these few cases has not been entirely consistent. This perhaps is comprehensible if one accepts the theory that ectasia is a secondary phenomenon depending on the degree of atelectasis and parenchymatous involvement.

SUMMARY

1 The various lobes from relatively early cases of bronchiectasis in children, for which lobectomy (and in 1 case pneumonectomy) had been performed, were dissected segmentally. The distribution of the lesions, as seen roentgenographically, is compared with the gross and microscopic findings.

2 Destructive lesions of bronchi, such as epithelial ulceration and destruction of muscle and elastica, were not a predominant feature.

3 Detailed microscopic examination showed definite if minimal inflammatory lesions of the segments which by bronchographic and gross examination appeared unaffected. These lesions are essentially similar to those found in the affected segments but it is impossible to draw any conclusions as to whether they are progressive or not.

4 The pathologic findings in this small series of cases have not been entirely consistent with the bronchographic appearance. This

understandable if ectasia is considered as a secondary phenomenon and if visible and definite involvement is not immediately present

5 Such findings point to the necessity of further detailed study of the various lung segments in bronchiectasis from the clinical, roentgenological, surgical, and pathological aspects

VAGOVAGAL REFLEXES

Electrocardiographic Changes During Vagotomy

MILES J GULLICKSON, M D, JAMES H McRAE, M D, and
DARRELL A CAMPBELL, M D, F A C S, Eloise, Michigan

CASES of sudden death due to cardiac or respiratory arrest coincident with manipulation of a vagus nerve or its branches during surgery in the neck or thorax have been reported (3). While direct stimulation of cardiac vagal fibers may have occurred, it is the opinion of some (22) that the majority of vagal stimuli, even those arising above the cardiac branches, result in an impulse which takes an afferent path to the medulla. An efferent impulse, completing a reflex, may then return over vagal fibers causing cardiac inhibition. This may be considered an example of a true vagovagal reflex in contrast to some partially nonvagal reflex arcs in which the impulse traverses other than vagus pathways for a portion of the arc.

Operations in which the procedure traumatizes the vagi between the pulmonary plexus and the stomach have increased with the revival of vagotomy for the surgical therapy of duodenal ulcer. To date only 1 apparently authentic case of a vagovagal reflex resulting in cardiac arrest and death during vagotomy has been reported (21). A previous incident in which vagovagal reflexes may have initiated an unfavorable postoperative course which shortly terminated in death has been recorded by Moore and associates.

From the Department of Surgery, Wayne County General Hospital, Eloise, Michigan.

Development of the various types of anesthesia in use today has necessitated an evaluation of the effects of preanesthetic and anesthetic medications on cardiac function. These alterations have frequently been conveniently recorded by means of the electrocardiogram. The difficulty of dissociating the effects of surgical manipulation from those specifically resulting from the anesthetic itself have been commented on in these reports, and the predominant role of the vagus nerves in the transmission of the afferent or efferent impulse, or both, has been emphasized.

Electrocardiographic alterations in specific relation to the operation of vagotomy for duodenal ulcer are of interest in further investigation of this problem. These changes would be expected to be subclinical in nature, but might indicate, to some extent, the possibility of more serious sequelae to a vagovagal reflex.

ELECTROCARDIOGRAPHIC OBSERVATIONS
DURING VAGOTOMY

Bilateral vagotomy between the pulmonary plexus and the stomach, by a left transthoracic approach, was done on 10 dogs. Another procedure to be described later, which also involved the vagus nerves, was performed on 3 additional animals. No premedication was given and endotracheal ether anesthesia was employed. Anesthesia was maintained at an even depth throughout operation. Standard

Fig. 1 Diagrammatic sketch of principal vagus paths

lead II was utilized in all cases, with the dogs in the right lateral position. Tracings were taken almost constantly, and always during manipulations involving viscera or vagus nerve trunks.

Electrocardiograms were also taken in the cases of 10 humans before, during, and after bilateral vagotomy for duodenal or marginal ulcer. In 4 of these the electrocardiographic tracings during portions of the operative procedure were not entirely satisfactory, and the possibility of transient changes of undetermined type was present. In 6 cases records were complete in every respect. In 5 of these transabdominal operations were performed and in 1 transthoracic was carried out. The usual preanesthetic medications were given, since they do not entirely abolish subclinical changes in cardiac function which occur during surgery and anesthesia.

TABLE I—ELECTROCARDIOGRAPHIC CHANGES OBSERVED IN 13 DOGS AND 6 HUMANS DURING OPERATIONS INVOLVING SECTION (10 ANIMALS AND 6 HUMANS) OR ISOLATION (3 ANIMALS) OF THE GASTRIC VAGI

Types of electrocardiographic changes observed	No animal		No human	
	Total No each change noted	No related to vagal stimulus	Total No each change noted	No related to vagal stimulus
Decrease in heart rate	1	1		
Decrease in amplitude, notch, or inversion of P wave	1			
Increase or decrease in amplitude of R wave	1			
Prolongation of P-R interval	0	1	1	1
Dissociation phenomena		1	1	1
Nodal rhythm			1	
Sino auricular pause	1	1		
Sinus arrhythmia	6	1	1	
Premature beats	2		1	
Flattening or inversion of T waves	3			

All electrocardiographic records taken in the period after induction of anesthesia and before beginning the operative procedure were normal. On 11 occasions during the operative procedures on 5 animals, decreases in rate, changes in amplitude or inversion of the P wave, variations of the P-R interval, dissociation phenomena, or sinus arrhythmia at sino-auricular block, were thought to have been specifically related to manipulation of the vagus. Similar and other changes also occurred without relation to visceral or vagal stimulation. All changes observed during operation without exception reverted to normal simultaneously with or shortly after closing the chest. Factors such as artificial respiration, direct stimulation of the heart, endotracheal intubation, and irritant effects of anesthetic vapors cannot be entirely eliminated.

Changes apparently related to handling of the vagus nerve occurred in 2 human cases. The changes consisted of a lengthening of the P interval. Other electrocardiographic abnormalities seen in the humans were not related to a specific mechanical stimulus. In only 1 case did any electrocardiographic changes

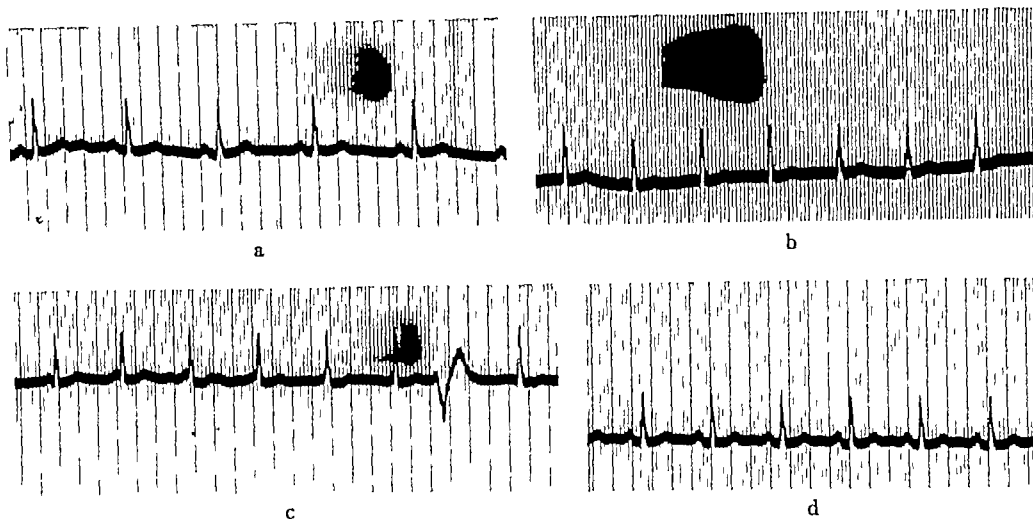

Fig 2 S W, 50 year old white male Transabdominal vagotomy for peptic ulcer Standard lead II a, Patient under ether anesthesia prior to surgery, sinus rhythm b, During manipulations of esophagus preparatory to isolation of vagi Middle nodal rhythm The fifth complex is suggestive of a low nodal beat with inverted P wave superimposed on T wave c, Recorded shortly after b Interference dissociation with 1 ventricular premature beat d, Immediately postoperative, sinus rhythm

show in the postoperative tracings. This patient had a normal preoperative electrocardiogram, but demonstrated an inverted *P* wave during most of the time that a vagotomy was being done. This reverted to normal before the patient left the operating table, and remained so the next day. Electrocardiograms taken on the second, third, fourth, and fifth postoperative days showed a reappearance of the inverted *P* wave. Explanation of this single instance of change in the postoperative tracings would be purely speculative.

If electrocardiographic abnormalities were noted they usually occurred early in the operation about the time that the first exploratory movements for the nerves were being made. Opening of the chest in the animals was never immediately followed by change in the electrocardiogram. When major changes in cardiac rhythm appeared they exhibited a definite tendency to persist throughout the remainder of the operation, and additional manipulation of viscera or nerve trunks failed to induce further change. There was no apparent relation to duration or depth of anesthesia.

In 3 animals bipolar electrodes attached to insulated wires leading from the chest were secured to one of the vagal trunks along the lower esophagus. Electrocardiographic trac-

ings were taken during surgery while the animals were under endotracheal ether anesthesia and repeated 24 hours later without anesthesia. Two animals showed no significant electrocardiographic change either during the operative procedure or during mechanical and faradic stimulation of the vagus 24 hours later. The third animal showed nodal rhythm and dissociation phenomena when traction was applied to the left vagus and this abnormality persisted until shortly after the chest was closed. Twenty-four hours later, without anesthesia, mechanical and faradic stimulation of the vagus caused a slight decrease in the amplitude of the *P* wave, occasional premature beats, sinus arrhythmia, and a brief sinoauricular pause. Conclusive evidence that cardiac effects will usually follow stimulation of the gastric vagi in the absence of anesthesia was not obtained from these experiments.

DISCUSSION

The numerous electrocardiographic studies which have been recorded during surgery and anesthesia are in some disagreement concerning the relative importance of visceral stimulation and that of the anesthetic in initiating these alterations. Some have felt that the anesthetic was the predominant fac-

Fig 3 Dog No 5 Endotracheal ether anesthesia Standard lead II Dog in right lateral position a, Surgical anesthesia prior to surgery, sinus rhythm, rate approximately 215 b, Changes occurring during manipulation of esophagus preparatory to isolation of the nerves (left thoracic incision, positive pressure anesthesia) *P* wave changes in first three complexes suggest shift in sino auricular pace maker followed by a middle nodal escape and midnodal rhythm for 2 beats The sixth complex is a lower nodal beat The impulse for the last complex arose in the sino-auricular node Rate decreased from approximately 104 to 42 These changes persisted throughout surgery and were not influenced by actual clamping or traction of vagi c, Vagotomy completed, chest still open Variation in shape of *P* waves indicates shifting pacemaker in sino-auricular node There is a period of sino-auricular block after the sixth complex followed by return to sinus rhythm Variations in height of *R* waves may be attributed to respiratory effect d, Chest closed, surgical anesthesia maintained, sinus rhythm, rate approximately 166

tor (12), while others have indicated the frequent relation of the electrocardiographic changes to operative manipulation (10) The occurrence of cardiac abnormalities with anesthesia only, during anesthesia before beginning an operative procedure, and after conclusion of an operation, indicates that manipulation is not a prerequisite However, in many instances, there undoubtedly is a relationship between the manipulation and the cardiac changes The results in this series emphasize the etiological importance of mechanical stimuli occurring during surgery It is also probable that the anesthetic sensitizes certain tissues, and the result is a response to stimuli which would otherwise be ineffective (14)

The fact that in a few instances stimulation of the gastric vagi seemed directly to initiate alterations in cardiac rhythm suggests that the vagi serve as the afferent path for some viscerocardiac reflexes Such reflexes are more frequently associated with surgery in the upper abdomen, where vagal endings are more numerous than in the lower abdomen It has been shown experimentally that cardiac inhibition produced by stimulation of exposed

viscera can be prevented by section of the gastric vagi (5), but confirmation is lacking in man That afferent pathways other than vagal may be utilized is demonstrated by the association of viscerocardiac reflexes with stimulation of areas in which there are no vagal endings (10, 12)

The similarity of the electrocardiographic changes which occurred during this series of vagotomies to those resulting from vagal stimulation proximal to the heart is striking Proximal vagal stimulation has been known to cause sinus arrhythmia, bradycardia, cardiac arrest, changes in the *P* wave, such as flattening, notching, and inversion, prolongation of the *P-R* interval, dissociation phenomena, nodal rhythm, complete auriculoventricular block, premature contractions, variations in the amplitude of the *R* wave, and flattening to the *T* wave All operative procedures in this series interrupted the vagi distal to the pulmonary plexus, and no specific vagal stimulation other than that usually incident to a vagotomy was done Nevertheless, all the changes, without exception, which were cited previously as occurring after stimulation of

Fig 4 Dog No 10 Endotracheal ether anesthesia Dog in right lateral position Standard lead II a, Dog anesthetized prior to surgery, sinus rhythm, rate approximately 214 b, Left thoracic incision, positive pressure anesthesia The first two complexes represent sinus beats At point indicated by arrow left vagus nerve traction was applied Immediately thereafter numerous artifacts are recorded but interference dissociation is noted to be present c, Recorded several minutes after b Middle nodal rhythm with phasic respiratory variations in QRS voltage d,

the proximal portion of the vagus, were seen at least once in this series of electrocardiographic tracings

The clinical importance of these electrocardiographic changes should not be overestimated Alterations in cardiac rhythm have been seen following gaseous eructations, nausea and vomiting, passage of gastric tubes, bronchoscopes, and endotracheal tubes, and deep respirations

Cardiac abnormalities resulting from anesthesia are not only due to the direct effects of the anesthetic on the heart In addition to increased sensitivity and irritability of cardiac tissue, changes in the physiologic efficiency of the conduction mechanism and alterations in vagal tone are conditions resulting from anesthesia which render the vagi and the heart more receptive to a given stimulus Recep-

tivity also varies among individuals, and in each individual at different times Since the type of anesthesia and preanesthetic medication chosen can usually be to some degree elective, it is of advantage to examine the experimental and clinical experience indicating that some anesthetic and preanesthetic medications have selective actions on the vagus mechanism and cardiac tissue, while others are less likely to be productive of cardiac abnormalities

Of the agents most frequently used in inhalation anesthesia, cyclopropane is well known as the chief offender in the production of cardiac irregularities While vagotomy did not abolish all such irregularities under cyclopropane anesthesia, an absence of increase in the *P-R* interval suggested that there was no disturbance in conduction (17) Few signifi-

cant electrocardiographic changes have been observed with the use of ethylene (10) or nitrous oxide, except for those associated with anoxia (20). Ether, a sympathomimetic agent, depresses vagal conduction (9, 19), but sensitizes the auriculo-ventricular node relatively more than the sino-auricular node, resulting in escape phenomena and shifting of the pacemaker (15).

Barbiturates decreased response to vagal stimulation but sodium pentothal (a thio-barbiturate) failed to demonstrate such a protective action (7). Though morphine has been said to increase vagal tone (17, 18), in the usual clinical dosage it may not be apparent (1). Any bradycardia resulting from the administration of morphine probably is a result of blocked cortical impulses which normally inhibit the vagal medullary center (2).

The effects of atropine in depressing the response to ordinary vagal stimuli are well known, but Lennox and Levine found that the usual doses only decreased electrocardiographic changes by one-half. Small doses are ineffective in achieving complete vagal paralysis and if this drug is being used to afford protection from the effects of vagal stimulation, a combined total of preanesthetic and intravenous doses should be 15 to 20 milligrams. Actual stimulation of the vagus center may be the initial result of small doses of atropine.

Experimentally, curare rendered the heart unresponsive to vagal stimulation (4), though ineffective in the presence of asphyxia (13).

An immense number of gastric resections and numerous experimental procedures requiring section of the gastric vagi have been done. The rarity of reports of clinically apparent cardiac derangements immediately resulting from these procedures makes the danger of a vagovagal reflex seem slight indeed. It is possible that vagovagal reflexes of a serious nature occur more often with surgery involving the more proximal portions of the vagi.

If precautions to avoid an occasional mishap during vagotomy are to be taken, certain recommendations can be made. These are selected after a consideration of some known specific actions, some of which are described

in the preceding paragraphs, of the agent's common use during surgery. The effects of these drugs on vagal conduction would seem relatively more important than their action on the intrinsic tissue of the heart, in evaluating their worth in the prevention of vagal reflexes.

1 Barbiturates and atropine are indicated for preanesthetic medication. Morphine probably best omitted.

2 Ether is the anesthetic of choice.

3 If curare is employed during the operative procedure it can be counted on to afford additional protection.

4 Good oxygenation is imperative.

5 Atropine, in adequate dosage, should be administered intravenously before search for the vagi is begun.

6 Procainization of the vagal trunks is necessarily preceded by mechanical stimulation incident to isolation of the nerves and is of little prophylactic value.

7 A section of the nerves should be carried out with a minimum of traction or other trauma.

8 Ligation of the central ends of the nerves should not be done routinely. It has been noted that ligation (6) and pinching the nerves with forceps (8) effectively initiated afferent stimuli.

CONCLUSIONS AND SUMMARY

1 Numerous reports indicate that subclinical changes in cardiac function, as determined by electrocardiography, frequently occur during surgery and anesthesia.

2 Observations on a small series of clinical and experimental cases during section of the gastric vagi demonstrated that electrocardiographic changes similar to those previously observed during other surgical procedures are not uncommon.

3 The comparative frequency of the subclinical derangements in cardiac rhythm is not a true indication of the relative incidence of vagovagal reflexes which would result in serious cardiac disturbances. The danger of such an occurrence during vagotomy for peptic ulcer is remote.

4 If the maximum precautions available are desired, recommendations concerning pre-

medication, anesthesia, and avoidable mechanical stimuli during operation have been made

5 The preceding conclusions and recommendations may only be applicable to cases in which the vagal stimulus arises below the pulmonary plexus

EFFECT OF PANCREATIC JUICE ON THE GALL BLADDER

STEPHEN E. REID, B.S., M.S., M.D., Evanston, Illinois

SINCE the main pancreatic duct empties into the duodenum in conjunction with the common bile duct, an ampulla of variable length is formed. Conceivably, conditions are present for an obstruction of the ampulla to create a continuous pathway between the biliary system and the pancreas (Fig. 1). The causes of obstruction have been listed as resulting from stones (24), spasm of the sphincter of Oddi (3), and acute edema of duodenal mucosa in the region of the ampulla (5). A continuous pathway can be demonstrated clinically by cholangiography. Dye injected into a T tube will sometimes fill the main pancreatic duct when the ampulla is obstructed.

DIRECTION OF FLOW

If a common channel of the biliary tract and pancreas is formed, the question arises: Will pancreatic juice reach the gall bladder? The pressure in the two systems has been measured in the experimental animal by many investigators (18, 19, 21, 27, 17, 14, 28), and the secretory pressure of the liver was found to equal that in the pancreas. These changed with the varied stages of digestion. Wolfer (36) introduced India ink into the terminal end of the common bile duct and found that at times it reached the gall bladder.

Clinically there is evidence to show that pancreatic juice can reach the gall bladder. Seifert observed diastase in bile in a clinical case. Walters and Marshall reported 4 cases in which pancreatic juice drained from a T tube, with resulting skin digestion. Popper (25) reported an analysis of bile for pancreatic ferments in 219 operative cases. Seventeen per cent showed increased diastase values, but 7 per cent were in cases of pancreatitis. In 36 of the cases bile was obtained by puncture of the gall bladder in the course of operations for conditions unrelated to the biliary tract or pancreas. In 3 of these, pancreatic ferments were obtained.

PATHOLOGY

If it is assumed, then, that pancreatic juice does reach the gall bladder, will pathologic changes result? It is known that active pancreatic juice can digest living tissue, as is demonstrated in the skin surrounding a high intestinal fistula. One would expect the gall bladder to be attacked by these enzymes, since this viscus is a very delicate structure. Schonbauer reported a case of gangrenous cholecystitis with biliary exudate in the peritoneal cavity. Trypsin was present in the bile. Westphal introduced duodenal secretions into the gall bladder in dogs and produced changes which in some approached necrosis. Wolfer (37) introduced pancreatic juice into gall bladder in dogs in a variety of ways and produced a pathologic condition in all instances, ranging from inflammatory cells, focal areas of necrosis with some evidence of regeneration to completely gangrenous structures. Andrews and his associates (2) tested the effect of pancreatic juice on the absorptive mechanism of the gall bladder. They used 19 dogs and injected pancreatic juice, either into the gall bladder directly with a needle or via a ureteral catheter up the common bile duct. All the gall bladders showed mild pathologic changes. Some of the juice was Berkefeld filtered, and less changes were produced in these instances than in those injected with unfiltered juice. Brackertz studied the effect of pancreatic juice on rabbits' gall bladders. He concluded that active sterile pancreatic extract alone had no effect on biliary passages within 12 hours. When colon bacilli were introduced with the pancreatic extract and when the common duct was ligated, digestive necrosis of the gall-bladder wall developed in every case within 12 hours. This necrosis was followed invariably by biliary peritonitis without macroscopic evidence of perforation. The extent of necrosis depended upon the activity of the pancreatic extract. The mucous membrane was attacked first. When pancreatic extract and colon bacilli were injected into the

biliary passages of rabbits without stasis, no change was noted in the gall bladder

Stulz and Bauer injected active pancreatic juice directly into the gall bladder in dogs and produced pathologic changes. They concluded that chronic changes occur when large amounts of pancreatic juice are injected into the gall bladder, but not necrosis. It must be assumed that the injection of large amounts of ferment means increased pressure within the gall bladder. This may, in itself, cause traumatic changes. Colp and his associates (13) reported 3 cases of free bile in the peritoneal cavity, with fat necrosis in 1. The gall-bladder bile was definitely alkaline in all 3. Diastase was present in large amounts in the bile aspirated from the 3 cases. They concluded that the pancreatic enzymes get to the gall bladder by reflux. The gall bladders showed acute ulcerative changes in the mucosa, and to a less extent throughout the wall. No actual perforation could be identified. They concluded that, if pancreatic juice is found in the gall bladder in such amounts as to change the pH to alkaline, digestion of gall bladder occurs.

Bisgard and Baker reported 2 cases of acute nonperforating gangrenous cholecystitis with regional bile peritonitis. Cultures from the abdominal fluid, bile, and gall-bladder contents were sterile, but the gall-bladder bile in both cases contained amylase and trypsin. The peritoneal fluid was not examined for enzymes. They experimented on goats, and temporarily or permanently obstructed the common bile duct at various levels, either distal to the cystic duct or distal to the cystic and pancreatic ducts. The duct arrangement in goats is particularly well adapted to the experiment. It was concluded that neither stasis of bile nor reflux of pancreatic juice as a single factor was productive of cholecystitis, but when they were combined they produced permanent pathologic changes in the gall bladder. Their combination produced a complete or partial necrosis of the gall-bladder wall which was chemical and not infectious. In several goats there was a nonperforating biliary peritonitis. They concluded that filtered bile does not activate pancreatic enzymes.

Arnonson anastomosed the pancreatic duct to the gall bladder in 4 dogs. All remained

Fig. 1 The ampulla in the human—formed by the junction of the common bile duct and the main pancreatic duct.

well for 2 years. They were then sacrificed, and it was found that in 3 the anastomosis had scarred over, and in 1 the anastomosis was open. There were extensive adhesions between the gall bladder, pancreas, and duodenum. The gall bladder was dilated and contained 25 cubic centimeters of a grayish-brown cloudy fluid and 3 stones. Cultures of bile revealed *Staphylococcus aureus* and *Clostridium welchii*. Only slight changes were found in the gall-bladder wall, and the author concluded that this was because the pancreatic juice was very considerably diluted with bile. Gatch and his associates injected activated pancreatic juice into the ampulla of Vater in 3 dogs. In 1 the injection was under considerable force, and the dog died in 15 minutes. Beginning necrosis around the bile ducts in the liver was found. In the remaining 2 animals, the injection was made with moderate pressure, and only minor changes in the bile ducts resulted. The writers concluded that the pancreatic juice acted for only a short time and that great damage would result if stasis of bile had prolonged the action of the pancreatic juice. The mechanical effect of the increased intraductal pressure is a factor that must be reckoned with in this experiment.

Nonperforating biliary peritonitis, mentioned previously, is undoubtedly a definite

Fig 5 Dog No 60 Gall bladder 190 times Many acute inflammatory cells are seen

EXPERIMENT

An experimental procedure was designed to show the effect of pancreatic enzymes on the gall bladder under as nearly physiologic conditions as possible. Dr Andrew C Ivy suggested the procedure, which was followed throughout the experiment.

Average sized mongrel dogs were used. The abdomen was aseptically entered, the duodenum was brought out on the abdomen and the lesser pancreatic duct identified without jeopardizing the blood supply. The location of the papilla of Vater was estimated. Midway between the pancreatic duct and the papilla the duodenum was transected, the gastroduodenal vessels being avoided. About 3 centimeters distal to this point of section, the duodenum was again sectioned, and a short segment of bowel containing the pancreatic duct with the pancreas and blood supply intact was isolated (Fig 2). One end of this duodenal pouch was closed and the other was anastomosed to the fundus of the gall bladder. The continuity of the duodenum was then re-established. By this procedure the pancreatic juice entered the duodenal pouch in the normal manner, flowed over the gall-bladder mucosa and drained from the cystic duct into the duodenum. The duct of Wirsung in the dog plays a very minor role.

Dogs recovered and remained well. About 3 weeks later the cystic duct was cannulated and secretin was injected intravenously. The contents of the gall bladder were collected

and assayed for pancreatic juice. Sections of the liver, gall bladder, and pancreas were taken and the patency of the pancreatic duct was demonstrated (Fig 3). *No pathologic condition was found in the gall bladder in the 10 dogs in this first series.*

Another group of 10 dogs were subjected to the same preliminary procedures, but 3 weeks later the cystic duct was ligated. The animals became moribund within 100 hours. The contents of the gall bladder were assayed for pancreatic enzymes, the same sections were taken and the patency of the pancreatic duct was again demonstrated.

Results. Six dogs showed an acute reaction of the gall bladder (Figs 4 and 5), one having complete necrosis (Fig 6). Two dogs

MORBID FACTORS IN EXPERIMENTAL APPENDICITIS

CARLOS A TANTURI, M D , and RAYMOND E ANDERSON, M D , Chicago, Illinois

TO gain a more fundamental concept of the basic pathogenic pattern of appendicitis and its chief complicating factor, peritonitis, we have produced this disease experimentally in the dog with the purpose of analyzing those factors which play a role in the production of the morbid process. We have endeavored to evaluate the relative importance of various generalized and local elements associated with appendicitis. The ultimate aim has been to obtain sound experimental data which will be of value to the clinical surgeon in his understanding and treatment of appendicitis and peritonitis. The role of the sulfonamides, penicillin, and other antibiotics has not been considered. Our effort has been directed toward the underlying pathological pattern of the disease process in order to formulate certain principles upon which a rational use of these drugs may be based.

Although considerable experimental work on appendicitis has been undertaken, only a few examples need be cited as representative of two main theories which have evolved regarding the cause of death and pathogenesis of the disease. The first of these general concepts proposes that the local site of infection, the gangrenous appendix, is the focus from which the whole morbid process arises and any systemic alterations are the result, or reflection, of factors which have their origin at this point. The bacteria associated with this gangrenous process have been held responsible for the death of the animal because of a fulminating infection or toxemia. Those workers who have endeavored to show that bacterial toxins are of prime importance have produced only indirect evidence, by means of animal immunization and inoculation of the material in question. An equal number of workers have presented data to show that the products of autolytic digestion are of primary importance.

Regardless, however, of the factor, or combination of factors, which bring about the death of the animal, this general concept presents the local site of infection as the initiating factor in the disease mechanism.

The second hypothesis which has been presented as an explanation for the morbidity or mortality in appendicitis and peritonitis places the emphasis on generalized systemic alterations in the animal, factors which are either already present prior to the disease, or which are activated early in the process. The dys-equilibrium of circulating enzyme systems, or the depression of various hepatic functions, has been held responsible. When a sufficient alteration of the systemic processes has occurred, the animal is said to be in a morbid or moribund state.

Although no clear cut differentiation of these two general hypotheses has ever been presented, almost all the work which has been done on this subject can be placed in one or the other categories.

Our present study has been undertaken in an effort to obtain a clearer concept of which of these hypotheses is the more important and which factor, or factors, of that hypothesis are the most significant.

THE EXPERIMENTAL DISEASE

Any study of an experimental disease necessitates a careful observation of the normal progress of the disease in the animal used in the study. Since it was our objective to study those factors associated with morbidity or death arising from appendicitis, we endeavored to produce this disease as consistently as was possible in the dog.

In 1938, Bower and his co-workers (2) found that 50 per cent of dogs will recover spontaneously, with no treatment whatsoever, after the appendiceal blood supply and the base of the appendix have been ligated. In every case of recovery, a walled-off appendiceal abscess was found when the dog was sacrificed. Further investigation by the same

TABLE I — DISTRIBUTION OF DEATH IN SERIES I DOGS—CONTROL

Mortality, 75%, Average duration of life, 68 hours			
Survived— hours	No of dogs	Survived— hours	No of dogs
0 to 24	2	72 to 96	3
24 to 48	8	Over 96 hours	2
48 to 72	3	Lived	6

workers showed that by giving 54 cubic centimeters of castor oil immediately after operation the mortality rate was increased to 91.7 per cent, and in every case the animal died of a spreading peritonitis.

Twenty-four animals served as our control series. The dogs were given morphine followed by intravenous nembutal as an anesthetic agent. The abdomen was shaved clean and then painted with 1 per cent iodine followed by 70 per cent alcohol. Strict asepsis was followed throughout except that rubber gloves were not worn by the surgeon. A lower midline, or right rectus incision was made and the cecum and appendix mobilized (Fig. 1). All vessels of the appendix were clamped and ligated and a heavy cotton ligature was placed about the base of the organ. Care was taken not to rupture the serosa, and no further crushing of the appendix was done (Fig. 2). The abdomen was then closed in three layers with fine black silk. A gastric tube was placed in the stomach and 50 cubic centimeters of castor oil were given the dog immediately before returning him to the cage. No supportive treatment of any kind was given to the animals and they were disturbed only once a day during the morning when blood samples were drawn. Food and fluid were offered freely following surgery.

The mortality rate for this control series (series I dogs) was 75 per cent and the average duration of life of those animals which died was 68 hours (Table I).

By performing careful postmortem examination on all dead animals and by sacrificing others at appropriate times we were able to follow closely the progress of the pathological process.

Following recovery from the initial shock of the anesthesia and surgery the animals appeared to go into a lethargic state which slowly progressed until the animal eventually suc-

cumbed. This lethargy was associated with a gradually increasing tachycardia and, in many cases, a mild hyperpnea.

Pathologically, within 24 hours the appendix had become a loosely hanging, yellowish grey necrotic sac with little or no walling-off by the surrounding viscera or omentum. The abdominal cavity contained a small amount of bloody fluid but the abdominal viscera still had a normal glistening appearance (Figs. 3, 4). In this series of 18 control deaths, only two animals deviated from this pattern. One died after 25 hours and another after 26 hours. Both animals had ruptured appendices and peritonitis.

From 24 to 48 hours, the dogs entered the critical period of the disease and at that time the natural body defense mechanisms were brought into play. Early in this period the omentum and loops of bowel began to wall off the necrotic appendix and a thin layer of fibrin was laid down. A moderate amount of bloody gray fluid was present in the peritoneal cavity (Fig. 5).

The fate of the dog depended on a balance of factors operating during this period. If complete walling-off occurred at this stage the dog began to recover and survival resulted. If rupture of the appendix occurred before any significant walling-off had taken place, the animal died within 12 hours of a fulminating peritonitis. When a partial walling-off occurred, so as to prevent a rapid dissemination of the gangrenous material into the abdominal cavity, the dog continued to live past the 48 hour period and the eventual length of the survival appeared to be the reflection of the severity of those elements which operated during this stage. Eight of the control animals died during the period between 24 and 48 hours.

All of the animals which managed to survive beyond the 48 hours but then succumbed showed the same pathological picture. The peritonitis increased in severity and no further walling-off of the gangrenous area was seen as compared with the period up to 48 hours. The omentum was slimy and necrotic, the exudate darkly hemolytic and foul smelling, and the bowel was injected and dull in appearance (Fig. 6). Six of the control animals

died during the period from 48 to 96 hours. Only 2 lived beyond this time, 1 of which died after 104 hours and the other after 168 hours.

With this pathological pattern of response to the experimental disease as a background, the specific evaluation of generalized and local factors was undertaken.

GENERALIZED FACTORS IN EXPERIMENTAL APPENDICEAL PERITONITIS

In 1946, Kay and Lockwood (12, 13) made a careful study of various systemic alterations

occurring in experimental appendicitis in the dog. They concluded that this disease, "culminates in an acute toxemia characterized by profound disturbances in hemodynamic equilibrium and in impaired function of the liver, lungs and other vital organs." They also suggested that, "the outcome of the disease, regarding death or survival appears to be related more to factors inherent in the condition of the animal prior to the experiment than to any demonstrable bacteriologic or anatomic variation in the local lesions as between dying and surviving animals."

TABLE III — PLASMA PROTHROMBIN ALTERATIONS IN SERIES I

Fig 7 Technique used in measuring fibrinolysis. These tubes contain the fibrin clot of the dogs' plasma and have been incubated for 24 hours. Tube 1 contains 1 drop of saline. No fibrinolysis has occurred. This is a negative determination. Tube 2 contains 3 drops of saline. No fibrinolysis has occurred. This is also a negative determination. Tube 3 contains 1 drop of sac fluid. Partial lysis of the clot has occurred. Tube 4 contains 2 drops of a sac fluid. Partial lysis of the clot has occurred. Tube 5 contains 3 drops of sac fluid. Complete lysis of the clot has occurred. This is a positive determination.

ity was determined. Originally, we used the technique of Kay and Lockwood (12, 13) but found that consistent, similar results were obtained when using 0.5 cubic centimeter of oxalated plasma (1 part 0.1 molar sodium oxalate to 9 parts whole blood) and 0.5 cubic centimeter of 0.025 molar calcium chloride. The latter technique fitted our purpose better because the same reagents were also standardized for use in prothrombin determinations.

The clot thus formed was placed in a water bath at 37 degrees and observed for 48 hours. Determinations were not made past this period because the possibility of bacterial contamination might alter the interpretation.

If breaking up of the clot (lysis) occurred during this period, it was considered a positive result. If no lysis of the clot occurred it was recorded as negative (Fig 7).

The 24 dogs used in the control series were studied in this phase of the problem (Table II).

Of the 18 dogs which expired in the control series, only 7 (38.8%) showed fibrinolysis at some period postoperatively and 11 showed no lysis. Of the 7 dogs showing fibrinolysis, 3 showed spontaneous lysis prior to surgery. One other dog displayed spontaneous lysis prior to surgery but showed none postoperatively. These 3 dogs died at an earlier period (37 hours) than the remainder (71.3 hours).

Of the 6 dogs which survived, 1 showed fibrinolysis in the postoperative period.

Prothrombin. Prothrombin determinations were made on 13 of the control animals according to the technique of Tanturi and Banfi.

the activation of an enzyme precursor, present in normal plasma, by filtrates of streptococci, and have proved that this enzyme so activated (activated lysin factor), although proteolytic, is not trypsin. Goodpasture found that specimens of blood from patients with atrophic hepatic cirrhosis possess the property of completely digesting their clot within a few hours at room temperature. Macfarlane's work (16) on fibrinolysis has shown that this phenomenon occurs after surgical operations, exercise, and adrenalin injection.

Since it was our purpose in this portion of the study to evaluate the importance of generalized factors relative to the mortality of the disease, we studied the possible alterations in prothrombin and fibrinolysis as a manifestation of systemic changes of the animal. One other criterion was added, the direct microscopic examination of the liver of the animals. Thus, any direct injury could be detected even in the event that functional derangement was not reflected.

Fibrinolysis. Prior to surgery and every 24 hours thereafter until the dog either expired or recovered, plasma fibrinolytic activ-

 Average prothrombin at 24 hrs — 74.4 per cent in dying animals
 D death

The prothrombin concentration was reduced postoperatively in all 13 animals (Table III)

Nine of the dogs which expired were in this group of 13 animals. In 2 of these dogs the lowest prothrombin was recorded at 48 hours and 1 of them died at 50 hours. In 7 instances it was lowest at 24 hours and in 3 of the dogs this was a single determination because the animals had expired before 48 hours. However, in 53.3 per cent of the animals studied beyond 48 hours the lowest prothrombin was not seen at the time of death.

The possible correlation between plasma fibrinolytic activity and hypoprothrombinemia

was checked on these 13 animals. In only cases (15.4%) did fibrinolysis occur at the time of lowest prothrombin level recorded.

The average drop in prothrombin at 48 hours was higher in those animals which died (49.8%) than in those which survived (14.4%), but in none of the dogs did the hypoprothrombinemia ever reach hemorrhagic levels.

Liver studies. The third factor studied as a means of determining systemic alteration in the disease was the direct microscopic examination of liver sections taken from dogs at various periods postoperatively. In the 13 animals whose autopsies were performed

Fig 8 Photomicrograph of a section taken from the liver of a dog dying of appendicitis with peritonitis at 26 hours. Section removed within 30 minutes of dog's death. No evidence of acute degeneration in liver. Some dilatation of the hepatic sinusoids, with an active congestion is seen.

Fig 9 Photomicrograph of a section taken from the liver of a dog dying of appendicitis with peritonitis at 54 hours. The histological picture of this section differs in no respect from that seen in the section taken from the dog dying at 26 hours.

formed shortly after death were considered. In no case could the amount of liver injury observed be considered as sufficient to cause the death of the animal. The general picture was that of an active congestion, dilatation of the sinusoids, and microvacuolation of the hepatic cells. The nuclei of the cells were normal and no type of acute degenerative process was identified (Figs 8, 9, 10a and b).

Chloroform intoxication. In an attempt to alter the fibrinolytic-antifibrinolytic equilibrium and prothrombin values in a group of animals at the time of surgery, 15 minutes of intratracheal chloroform was given to 10 dogs immediately following the procedure (series II dogs). This hepatic damage was produced in order to handicap the animals as they entered

the crisis of the disease. Thus, early manifestations of derangement of the prothrombin and fibrinolytic values could be expected.

Eight of the 10 animals expired, a mortality of 80 per cent as compared with our control mortality of 75 per cent. However, the average duration of life was 42 hours, as compared with the average of 68 hours in our control series (Table IV).

Spontaneous fibrinolysis was seen prior to surgery in 3 animals, but only one of these showed lysis in the postoperative period and this animal died. The only other animal showing any fibrinolysis in the postoperative period survived. These figures show no significant deviation from those seen in the control animals.

Fig 10 a, left Photomicrograph of a section taken from the liver of a dog dying of appendicitis with peritonitis at 104 hours. There is some microvacuolation of the hepatic cells in this section but the general histological picture does

not differ from that seen in the liver of dogs dying at an earlier period. b, High power magnification of the same section as Figure 10a. There is no evidence of nuclear change in this section.

Fig 11 a, left Photomicrograph of a section taken from the liver of a dog dying of appendicitis with peritonitis at 30 hours This dog was subjected to 15 minutes of intratracheal chloroform during the production of the

disease There is no evidence of acute degeneration of this liver b, High power magnification of the same section as Figure 11a There is no evidence of nuclear change in this liver

Twenty-four hours after surgery the average prothrombin level in the dying chloroform treated animals was 74.4 per cent, as compared with a figure of 59.9 per cent in the control group.

It appears that the added effect of chloroform inhalation for 15 minutes to the intoxication of appendicitis does not produce liver injury. As the maximum reduction in prothrombin due to chloroform intoxication in normal animals is reflected at 48 hours, the shorter survival produced by chloroform in the appendiceal peritonitis dogs is due to factors not reflected in variation in prothrombin. The animals die in a period too early for this reflection to be identified.

Liver studies on sections taken from these chloroform treated animals did not differ from the histological picture of the control dogs, since death intervened before any significant necrosis due to the chloroform had occurred (Figs 11a and b).

LOCAL FACTORS IN EXPERIMENTAL APPENDICEAL PERITONITIS

Among those workers who have stressed the importance of the local gangrenous process in the mortality of this disease, there is no agreement as to what factor, or combination of factors, is of the most importance. In 1938 Bower and his co-workers (1, 10, 11) published several reports on experimental appendicitis

in the dog and their conclusions pointed to the organisms of the clostridium group as being of significance. The mortality of the disease was reduced from 74.2 per cent in the control groups to 33.3 per cent in groups which had been given a commercial preparation of gas gangrene antitoxin therapeutically. They were also able to reduce the mortality in pigeons inoculated with *Clostridium welchii* extracts after they had been given injections of lyophilized convalescent serum of their recovered experimental dogs.

In past years other workers have approached the problem of the cause of death from gangrenous intraperitoneal lesions in a variety of ways. Some claim that a bacterial toxin is the chief offender (21, 22, 27), others place the emphasis on products of protein digestion or tissue autolysis (4, 26). All the investigators have substantial indirect evidence to support their claims.

From the pathological studies on the control animals, one fact remained very consistent. Those animals which were able to wall off the gangrenous appendix early in the disease process survived, whereas those animals unable to do this at an early period eventually expired. This pointed out the necessity of studying carefully that material, whatever it be, which was produced by the appendiceal appendage as it passed through the stages of necrosis and gangrene. Perhaps

Fig 12, left The polythene sac as it is placed over the ligated appendix and sutured to the cecum

Fig 13 The same polythene sac as shown in Figure 12, 72 hours later. The dark gangrenous material in the sac was the object of the analysis of local factors associated with appendicitis

in this material lay the key to an understanding of why some animals could wall-off the appendix and others could present no barrier to the process

Although the placing of various types of bags over strangulated portions of intestine have been carried out by several workers (1, 14), a new technique was devised by us in order to wall-off artificially the gangrenous appendix and study the material produced in the process. Polythene (polyethylene) sheeting was vulcanized into a small water tight sac, and after ligation of the appendix in the same manner as was done in the control series, this sac was placed over the appendix and sutured snugly to the cecum (Fig 12). The omentum was then tacked down about the base of this sac in order to prevent any possible leakage. Fifty cubic centimeters of castor oil were given to the dog, exactly as was done in the control group. The dogs were then reoperated upon at appropriate periods. The sac was removed and the gangrenous stump or fecal fistula, whichever the case, was closed with black silk. The omentum was again tacked down over this area. No antibiotics or supportive therapy of any kind were given. The sac fluid was then analyzed according to the technique described below.

This group (series III dogs) consisted of 12 control animals which were reoperated upon at 72 hours. This hour was chosen so as to correspond as closely as was practical with the average life span in our control series.

Of the 12 dogs subjected to this procedure, 1 died prior to the second operation presenting a mortality of only 8.3 per cent.

Among the 11 animals which underwent the second procedure, there were no postoperative deaths. Thus, 11 of 12 animals were saved by the simple expedient of artificially walling-off the local inflammatory process.

None of the dogs with the sac-covered, gangrenous appendix which had undergone the second procedure showed any evidence of generalized peritonitis. The sac, however, invariably contained from 25 to 50 cubic centimeters of dark, hemolytic, foul-smelling fluid along with the slimy, necrotic appendix (Fig 13). In most cases a substantial layer of fibrin had been laid down about the suture line at the base of the sac. Occasionally, the omentum appeared friable near its proximity to the suture line.

The fluid contained in the sac was measured into a series of centrifuge tubes and turned at 1500 r.p.m. for about 10 minutes to remove most of the particulate matter. The supernatant fluid was then passed through a Seitz filter, and the bacteria-free residue was the object of our investigation.

Fibrinolysis Since it was not our purpose in this phase of the experiment to repeat any controversial work in order to add further evidence to one side or the other, we approached the analysis of this fluid from another direction. Our investigations had shown that the production of fibrin about the local area

was one of the important factors associated with ability to wall-off the gangrenous appendix. The inability of the animal to present a fibrin barrier, or the dissolution of any fibrin produced about the gangrenous appendix, meant certain death for the dog. Our first analysis, therefore, involved the attempt to identify the presence of a fibrinolysin in the local fluid.

The method of detecting an activator of the lysin factor involved setting up a series of 3 tubes for each animal.

Tube 1—0.5 cubic centimeter of plasma plus 0.5 cubic centimeter of calcium chloride plus 3 drops of saline.

Tube 2—0.5 cubic centimeter of plasma plus 0.5 cubic centimeter of calcium chloride plus 1 drop sac fluid, plus 2 drops saline.

Tube 3—0.5 cubic centimeter of plasma plus 0.5 cubic centimeter of calcium chloride plus 3 drops sac fluid.

These were incubated for 24 hours and lysis was recorded as follows: lysis in Tube 2 equals 2 plus, lysis in both tubes equals 3 plus, partial lysis in either tube equals 1 plus. Lysis in control tubes was also noted, but in every case this corresponded with the activity of the dog's serum at the time of surgery (Fig. 7).

Eleven animals were studied in this way (Table V). Eight (72.7%) showed lysis in one or both tubes, 1 (9.1%) showed only partial lysis, and 2 (18.1%) showed no lysis. Only 1 of the dogs in this series of 11 showed partial lysis in the plasma at the time the sac was removed.

Samples of peritoneal exudate from 11 dogs in a plain appendicitis series which had been reoperated upon at various periods following production of the disease (series IV) were also studied for fibrinolysis. Six of these fluids showed no fibrinolysis, 4 showed partial lysis, and 1 showed complete lysis of the clot. The plasma of none of the animals showed spontaneous lysis in the control tube (Table V).

Hyaluronidase. The basis for our second analysis arose from a study of the pathogenesis of the local process. Unless the animal can naturally wall-off the area of gangrenous appendix early in the disease, a steady progression of events takes place which eventually ends in the death of the animal. This would indicate that some product relentlessly breaks down all natural barriers once it is present in sufficient amounts. Such a spreading factor has been identified in many types of infection (5, 8), and recently (11, 17) the enzyme hyaluronidase has been named as one of the chief components of this spreading factor in streptococcus, staphylococcus, and clostrid.

Fig 14 The mucin clot prevention method of determining presence of hyaluronidase. Increasing amounts of the exudate from 0.31 cubic centimeter in tube 1 to 0.5 cubic centimeter in tube 5 have been added to the potassium hyaluronate solutions and incubated 20 minutes. The absence of the mucin clot in the tubes of higher concentration of the exudate indicates that digestion by the enzyme has occurred.

Fig 15 Photomicrograph of a smear taken from the sac fluid at 72 hours and stained by the Gram technique.

um infections. The identification of this enzyme in the products of a gangrenous appendix was, therefore, the object of the second analysis.

Hyaluronidase determinations were done by mucin clot prevention method of McClean (18) serial dilutions of the material from 1:2 to 1:32 in 5 tubes being used. Values were recorded as units corresponding to the number of the tube of highest dilution in which the enzyme appeared, 5 being the highest figure (Fig 14).

The sac fluid from 6 dogs was studied in this phase of the work. All of the fluid contained the enzyme, 5 (83.3%) of them in amounts detectable in 0.31 cubic centimeter of the exudate (Table V).

To compare the amount of hyaluronidase present in the localized process with that found in the abdominal cavity during generalized peritonitis, samples of exudate from dogs in series IV (plain appendicitis reoperated upon) were studied for the enzyme. Eleven such exudates were analyzed and in only 3 cases was any enzyme detected. These figures are stated in Table V.

Lecithinase. Our third investigation was undertaken because of our interpretation of the clinical picture and pathological state in the dying animals, plus the examination of smears taken from the gangrenous exudate. The tachycardia, hyperpnea, and weakness seen in the moribund animals plus the severe, hemolytic type of peritonitis, the slimy gangrenous omentum and presence of gas in the

peritoneal cavity combined with the presence in almost every instance of a gram positive rod-shaped bacillus on smears (Fig 15) led us to the belief that a toxin, probably that elaborated by one of the anaerobic bacilli, was of significant importance.

Although many workers have been in accord with this theory, their evidence has been based on observations dependent on the protection of small animals with commercial or prepared gas gangrene antitoxin before or after the gangrenous material had been injected. Such a technique, although very accurately and skillfully done, presents many variables which may alter the evidence and is, in a fundamental sense, only indirect proof of the existence of a specific toxin.

In order to avoid these factors, our experiment was aimed at a direct titration of the toxin of *Clostridium welchii* from the gangrenous material. Recently, several workers (15, 25) have identified the enzyme lecithinase as being the lethal toxin (alpha toxin) of the type A-*Clostridium welchii* organism. Our third analysis, therefore, was an attempt directly to identify this toxin in the gangrenous material.

McClean's original technique for the detection of the toxin of *Clostridium welchii* (18) was modified somewhat by us and applied to the study of the appendiceal exudate. This procedure is based on the ability of lecithinase to produce a turbidity in a dilute egg yolk solution in the presence of calcium ions and is very specific and sensitive. Control tubes

Fig 16 Technique used in lecithinase determinations. These tubes have been incubated for 2 hours at 37 degrees Centigrade. Tube 1 contains 0.5 cubic centimeter of sac fluid. Turbidity is evident, proving the presence of *Clostridium toxin*. Tube 2 contains 0.5 cubic centimeter of sac fluid plus 1.0 cubic centimeter of convalescent dog serum. No turbidity is seen, indicating that this serum inhibits the toxin. Tube 3 contains 0.5 cubic centimeter of sac fluid plus 1.0 cubic centimeter of commercial polyvalent gas gangrene antitoxin. Turbidity is seen, indicating that this type of antiserum does not inhibit the toxin produced in the dog. Tube 4 contains 6 minimum lethal doses of *Clostridium welchii* toxin. Turbidity is apparent. Tube 5 contains 6 minimum lethal doses of *Clostridium welchii* toxin plus 1.0 cubic centimeter of commercial polyvalent gas gangrene antitoxin. No turbidity is seen, indicating that this antitoxin inhibits the commercially prepared toxin.

were set up with antitoxin and comparisons were made on a Coleman universal spectrophotometer using a monochromatic beam of 560 gamma.

Six sac fluids and 11 samples of peritoneal exudate in generalized peritonitis (series IV dogs) were analyzed in the original experiment. Standard polyvalent gas gangrene antitoxin was employed for the control standard in each of these experiments. Although turbidity appeared in several of these analyses, the turbidimetric differences recorded in the control and unknown tubes was of no significance, therefore we assumed that this turbidity was a constant factor and our results were recorded as negative in all 17 determinations (Table V).

Since several dogs which had recovered from the experimental diseases were available for further study, it was decided to titrate the antitoxic properties of their serum against the exudate and compare these results with those obtained with the commercial gas gangrene antitoxin.

The results in this experiment were quite different. It was found that although the commercial antitoxin had little or no effect in preventing turbidity, our dogs' convalescent

serum inhibited the toxin to such an extent that significant spectrophotometric differences were recorded (Fig 16).

Experimental appendicitis was then produced in another series of 16 dogs (series V). Polythene sacs were placed over the ligated appendix in 10 of these animals. One of these dogs died of pneumonia within 24 hours of the first procedure and was therefore discounted. Only 1 of the 9 animals subjected to the second procedure died.

The toxin of *Clostridium* was identified in 8 of the 9 sac fluids analyzed (88.8%) and the average turbidimetric reading was 60.1 per cent. Hyaluronidase was found in every fluid analyzed and in 5 instances (55.5%) was detected in less than 0.31 cubic centimeter. Streptokinase appeared in significant concentrations in 7 of the 9 sac fluids (77.7%). The figures are recorded in Table VI.

The general peritoneal exudate in 6 dogs of this series was also analyzed. Lecithinase was detected in 5 of the 6 animals (83.3%) and the average turbidimetric reading was 71 per cent. Hyaluronidase was detected in only 3 fluids. Of 5 exudates studied for fibrinolysin, 3 contained the enzyme in small amounts (Table VI).

Histamine studies. In an effort to evaluate the role of histamine shock as a factor in the death of the experimental animal and to compare the relative toxicity of sac fluid and known *Clostridium welchii* toxin, several dogs were subjected to injections of these fluids.

The general peritoneal exudate from 5 dogs with appendicitis was analyzed as to its histamine content, isolated guinea pigs not being used as a method of assay. Only one fluid of this group was shown to contain an appreciable amount of histamine or histamine-like substances.

Random samples of two of these fluids containing minimal amounts of histamine were then injected intravenously into 2 dogs and histamine release into the dogs' plasma was assayed. A significant release was observed in both animals.

Two animals were then selected for injections of *Clostridium welchii* alpha toxin intravenously. Histamine release was studied. A significant increase in plasma histamine

found in either case. In one of these animals careful blood studies were carried out. Blood was drawn from the heart just before the animal died. This blood failed to show any lysis in 48 hours. Prothrombin level at death was decreased, but this decrease was due to actual liver injury, as titration of the plasma against protamine showed no heparin release. Similar studies on a dog injected with sac fluid have shown lysis to occur and decrease in prothrombin in presence of heparin release.

Control studies on standard *Clostridium welchii* toxin and samples of fecal matter were carried out in order to evaluate the results of this experiment. No variation in these control analyses could be held responsible for the results in the experimental animals (Table VII).

DISCUSSION

tis to less than 4 deaths in 100,000, a basic knowledge of the pathogenesis of this disease is an essential aid to the surgeon. The indiscriminate use of these powerful weapons will never supplant sound surgical judgment based on a true understanding of the disease mechanism.

The complexity of factors associated with this disease has warranted considerable ex-

perimental work, and from this work has come a vast amount of knowledge concerning alterations in many of the physiological mechanisms of the experimental animal. Our present study has been undertaken in an effort to direct the attention of both the clinical and research surgeons to those factors which we believe are the most significant in the morbid process of appendicitis and peritonitis.

The systemic alterations seen in our experimental animals did not appear to be either of a severe enough degree, or consistently present, to designate such derangements as fundamental mechanisms in the morbid process.

The decrease in prothrombin seen in every animal postoperatively certainly points out some degree of liver injury. The greatest drop appeared in 24 hours in 55.5 per cent of the dying animals and in only 44.4 per cent of the animals did the lowest prothrombin concentration appear near the time of death. From these figures it cannot be said that alteration in prothrombin concentration is a predisposing factor in the death mechanism. It is more likely that a mild degree of liver injury manifested by prothrombin decrease is a reflection of some primary etiological factor.

There was no correlation between plasma fibrinolysis and death in our animals. Only 38.8 per cent of the dying animals showed any fibrinolysis postoperatively and 16.6 per cent of the living animals also displayed this phenomenon. The importance of such a factor necessarily must be secondary when its presence is identified in less than one-half of the dying animals.

The small percentage of animals (15.4%) showing fibrinolysis at the time of the lowest prothrombin level does not substantiate the theory that fibrinolytic enzymes in the blood destroy circulating prothrombin.

Microscopic examination of the liver in dying animals gave us no indication that hepatic damage could account for death. Nuclear disintegration or parenchymal injury were absent or minimal in every specimen studied. The congestion, dilatation of the sinusoids and microvacuolation, however, could very well be the response to a generalized toxemia. This amount of hepatic cellular damage probably

accounts for the decrease in circulating prothrombin, but cannot be held responsible for the mortality.

The earlier death in that group of animals subjected to chloroform intoxication cannot be attributed to any alteration in fibrinolytic antifibrinolytic equilibrium, or decrease in circulating prothrombin, since these phenomena were not in evidence at the time of the animals' deaths. Perhaps some synergistic action of the liposolvent properties of chloroform and lecithinase tend rapidly to overcome the natural defense of the animal. This question bears further investigation.

The importance of the local factors as initiating mechanisms for the production of death is emphasized since recovery can be obtained in more than 90 per cent of animals by artificially walling-off the local gangrenous process. In the natural course of the disease process, the animal would be faced with the problem of combating those factors which we have studied, thus the local area of gangrene assumes the importance of a battle ground on which the invasive forces and natural body defenses strive for survival or death.

The invasive and lethal properties of the local exudate are probably dependent on the synergy of the bacterial flora of the bowel when a suitable medium for growth is presented, namely, the gangrenous appendix. Synergism of the bacteria, we believe, is necessary for proper metabolic processes which eventuate in an increased toxicity of the local fluid (19).

The identification of an activator of the lysin factor in 80 per cent of the sac fluids suggests that this element of the local process may be significant. This enzyme is probably a product of streptococcal growth, streptokinase, and its ability to produce fibrinolytic properties in the local exudate indicates that a natural walling-off of the area by deposition of fibrin, may be a difficult thing for the host to accomplish. Then, too, the experimental studies of Grob have demonstrated that the products of protein digestion, present when fibrinolysis occurs, in addition to inhibiting the bacteriostatic action of sulfa drugs, also directly promotes bacterial growth. This fact may account not only for the inability of 75

BLOOD AND "AVAILABLE FLUID" (THIOCYANATE) VOLUME STUDIES IN SURGICAL PATIENTS

Part II Operative and Postoperative Blood Loss with Particular Emphasis Upon Uncompensated Red Cell Loss

JOSEPH R STANTON, M D, RICHARDS P LYON, M D, EDWARD D FREIS, M D,
and REGINALD H SMITHWICK, M D, F A C S, Boston, Massachusetts

IT is the responsibility of the surgeon to know the amount of blood a patient may lose as a result of an operative procedure. Studies of blood loss reported in the literature (1, 3, 13, 21, 22, 23, 25, 33-36) have been made by colorimetric or gravimetric measurement of the blood removed from the wound on towels and sponges and in the irrigating fluid during the operation. Such studies have led to the compilation of tables of average operative blood loss for different procedures (3, 5). It is the purpose of the present report to suggest that these figures may have given surgeons an unwarranted sense of security for two reasons: (1) the amount of blood removed from the wound at the time of operation may not represent the actual amount of blood lost to the circulation, and (2) postoperative blood loss may occur in amounts greater than the actual operative blood loss. This loss not infrequently results in uncompensated red cell loss.

In previous studies (12, 19) from this laboratory describing serial changes in the blood volume and available fluid in the postoperative surgical patient, large decreases in the postoperative red cell volume and hematocrit were not infrequently noted. These were of sufficient magnitude to lead us to question whether they could be accounted for by operative blood loss. Thomas, Adams, and Thornton, also utilizing the blood volume method in 5 patients undergoing thoracic

surgery, likewise noted decreases in the red cell volume even when adequate amounts of blood had been given by transfusion to replace the blood removed from the wound at operation. Thornton, Adams, and Schaefer and Lord and Hinton have noted that large amounts of plasma and red cells may be lost from and into the chest postoperatively. That the postoperative decreases in the red cell volume noted in this laboratory and by others might be accounted for by postoperative blood loss was deemed probable. It seemed desirable to reinvestigate the problem of blood loss, both that occurring during, as well as following, various operative procedures.

MATERIAL AND METHODS

The subjects of this study were a group of patients from the ward and private surgical services of the Massachusetts Memorial Hospitals.

Blood loss at operation (a) Gravimetric method. Gravimetric determinations of the blood lost in the packs and sponges were carried out according to the method described by Wangenstein. Where possible double layers of packs were sewed to the margin of the wound to prevent blood being absorbed on the drapes or towels. Blood on the gloves and instruments was removed as rapidly as accumulated by dry sponges. No saline irrigations or wet packs were used whenever this was feasible. When large walling off packs were moistened with saline they were discarded. The scales which were used in the weighing process read to an accuracy of 0.1 gram.

(b) Colorimetric method. The colorimetric determinations reported here were based on

From the Medical and Surgical Services, Evans Memorial Massachusetts Memorial Hospitals and the Departments of Medicine and Surgery, Boston University School of Medicine, Boston, Massachusetts.

This investigation was supported in part by the Squibb Institute for Medical Research, New Brunswick, New Jersey, and the Smithwick Foundation.

Presented in part before the Clinical Congress, American College of Surgeons, New York, September, 1947.

Fig 1 Graphic representation of results of three methods of studying blood loss at operation

a procedure modified from the acid hematin method of Gatch and Little. Oxyhemoglobin determinations were carried out on the Coleman junior spectrophotometer(2). A sample of 5 cubic centimeters of the patient's blood drawn preoperatively was diluted to 1000 cubic centimeters with distilled water and, upon being cleared with dilute ammonium hydroxide and filtered, was read on the log scale at a wave length of 540 millimicrons against distilled water. Properly diluted samples of the hemoglobin extracted from the sponges and towels were treated and read in the same fashion. With corrections for dilution the amount of blood lost was calculated by the following modification of the Lambert Beer law for spectrophotometric differences in optical density

$$C_2 = \frac{C_1 \times D_2}{D_1} \quad \text{where } C_2 = \text{concentration of unknown}$$

$$C_1 = \text{concentration of standard}$$

$$D_1 = \text{optical density of standard}$$

$$D_2 = \text{optical density of the unknown}$$

(c) Red cell volume method. In all cases serial blood volume studies were carried out in the preoperative and postoperative periods as detailed in the first paper of this series (19)

Total blood volume and red cell volume were determined from the plasma volume and hematocrit (14). In this paper all references to red cell volume refer to the red cell volume as determined by this method. All measurements of plasma volume were carried out in the basal postabsorptive state with the patient resting supine in bed for at least 2 hours prior to the test.

On experimental grounds (11, 15, 29) the objection may be raised that the red cell volume as measured by this method is about 15 per cent higher than the absolute red cell volume. Nonetheless, the same error is present in all determinations both preoperatively and postoperatively so that repeated determinations in the same patient should yield reliable information as to red cells lost or gained by the circulation.

In selected cases the plasma volume was determined in the preoperative and immediate postoperative periods. Since the plasma volume may change relatively rapidly in response to intravenous infusions or acute severe blood loss and thus alter the total blood volume, neither plasma volume nor total blood volume changes can be used as a reliable index of

TABLE I—BLOOD LOSS AT OPERATION IN 20 CASES, DETERMINED BY COLORIMETRIC OR GRAVIMETRIC METHODS

Case	Age	Sex	Operation	Operative blood loss c c
1	56	M	Subtotal gastrectomy	480*

*Gravimetric determinations

blood loss. Because the total red cell volume is resistant to changes resulting from hydrating or dehydrating procedures, this fraction of the blood volume was used to compute the amount of blood lost from the circulation as a consequence of the operative procedure. Similarly, postoperative blood loss was computed from the successive postoperative red cell volumes. In this manner blood lost at operation and blood lost postoperatively could be individually assayed.

RESULTS—OPERATIVE BLOOD LOSS

Table I illustrates the blood loss at operation in a series of 20 patients as determined

Blood on sponges
 Blood on drapes
 Blood on towels
 Blood on gloves
 Blood on gowns
 Blood on instruments
 Blood in surgical specimen
 Blood in wound not absorbed by sponges
 Blood lost to circulation through ligatures e g

Fig 2 Details of sources of loss measured by the red cell volume (T1824) method of studying operative blood loss

by the usual gravimetric or colorimetric methods. Although this series is relatively small the values for operative blood loss as measured by the classical methods do not differ significantly from those reported for comparable procedures in the literature. The operative blood loss in 5 cases undergoing lumbodorsal splanchnicectomy as described by Smithwick averaged 201 cubic centimeters at each stage.

The colorimetric method of determining blood loss contains a source of error in that it is based on hemoglobin determinations. Even using the photoelectric colorimeter Evelyn has reported an error of ± 2 per cent. More important than this are multiple other errors introduced by incomplete extraction of the hemoglobin from the sponges, by contamination of sponges with bile or iodine, and errors in the process of dilution which though small may greatly alter the final value.

In comparing the colorimetric and gravimetric methods for the measurement of the blood removed from the wound the gravimetric procedure yielded the more reliable results. However, this method also is subject to certain errors. Baronofsky and associates noted that small increments in weight may be due to tissue fluid absorbed by the sponge. In our experience with colorimetric studies on material which had previously been measured gravimetrically we were repeatedly impressed

Fig 3 Comparison of operative blood loss as studied by the colorimetric, gravimetric, and red cell volume methods in 2 cases

by the heavy layer of fat that rose to the top during the extraction process. This may be of importance in carrying out gravimetric blood loss studies in the obese patients in whom extensive dissection is carried out through fatty layers.

The question of errors due to evaporation also was investigated. In 4 experiments where 50 cubic centimeters of blood was placed on sponges and exposed to the air in the laboratory for 1 hour, the loss of weight by evaporation of water averaged 2.88 grams. Thus it may be assumed that in the operating room which maintains a relatively high humidity, errors from loss of weight by evaporation will be kept at a minimum if sponges are weighed within 15 minutes of the time of discard from the table.

In contrast to the colorimetric and gravimetric methods, the red cell volume method based on the principle of dilution of injected dye, measures the total volume of blood in the circulation. Inasmuch as there are no significant storehouses of red cells in the human body, serial measurements by this method reveal the total amounts of blood lost from the circulation as a result of the operative procedure (Figs. 1, 2). This includes not only the blood removed from the wound but in addition all blood lost in the surgical men, infiltrated into the wound and surrounding tissue spaces and not absorbed by coagulation or immobilized in vessels proximal to the incisions. It is evident that this method will yield higher values for the amount of blood lost than can be measured by either the colorimetric or gravimetric methods.

Fig 4 Thoracotomy with resection of lingular bronchus, postoperative blood loss, 1200 cubic centimeters. The difference between actual and theoretical red cell volumes on first postoperative day is 585 cubic centimeters of red cells or 1280 cubic centimeters of whole blood.

Theoretical red cell volume, which is indicated by the diagonally lined column, was computed in the manner which is described in the text. Note that the red cell volume has not returned to the preoperative levels at the end of 5 weeks' time.

imetric or gravimetric methods which measure only the blood removed from the wound on the sponges and towels.

Figure 3 represents a comparison of the three methods of studying blood loss in 2 cases. In both instances there was close agreement between the colorimetric and gravimetric methods which measure only the blood removed from the wound. The red cell volume method, which measures the blood lost to the circulation, yielded significantly higher values.

The method is particularly satisfactory where large amounts of blood are lost. It is useful both in measuring progressive loss and total depletions of the red cell volume and in evaluating replacement therapy. The chief difficulty with the red cell volume method is that it requires special apparatus and meticulous technique. While yielding satisfactory results as a clinical research method, it is at the present time too difficult technically to be considered practical for routine clinical use.

RESULTS—POSTOPERATIVE BLOOD LOSS

The red cell volumes studied serially in 4 cases at various intervals during the preoperative and postoperative periods are illustrated in Figures 4, 5, 6, and 7. It will be observed in Figures 4, 6, and 7 that striking diminutions in the red cell volume occurred. Blood loss at operation was studied in all cases by the gravimetric and colorimetric methods. On the basis of the total blood loss at operation multiplied by the preoperative hematocrit, the number of cubic centimeters of red cells lost at operation was computed.

The lightly stippled areas in each figure represent the actual red cell volume. The heavily lined column in each figure represents the theoretical red cell volume, i.e., the preoperative red cell volume (at 0 day) plus the red cell gain by transfusion and minus the red cell loss at operation computed from the colorimetric or gravimetric operative blood loss and the hematocrit. More specifically, in each case the theoretical red cell volume represents that which should have been present if

Fig 5 Cystectomy with ureteral implantation in the colon, postoperative blood loss, 1070 cubic centimeters. The difference between theoretical and measured red cell volumes on the fourth postoperative day is 473 cubic centimeters of red cells or 1070 cubic centimeters of whole blood. Operative and postoperative loss in this case were compensated for by early and adequate transfusion (1500 cubic centimeters).

no blood were lost other than that removed from the wound at the time of operation. The postoperative loss of whole blood is listed in the legend accompanying each figure and was computed from the difference between the theoretical red cell volume and the red cell volume actually measured by the dye method.

The first portion of this report introduced evidence to support the concept that the classical gravimetric and colorimetric methods do not measure all blood lost from the circulation at operation. It must be recognized, therefore, that a portion of the figure given as postoperative loss may represent additional operative loss not detected by the classical methods. However, as presented later, clinical evidence and autopsy findings support the statement that at least the major portion of the difference between the theoretical and actually determined red cell volume represents the previously unquantitated phenomenon of postoperative red cell loss.

Figure 4 illustrates a thoracotomy with resection of the lingular bronchus. Operative blood loss was 670 cubic centimeters of whole blood replaced with 1000 cubic centimeters by transfusion. Replacement therapy should have been more than adequate. The theoretical red cell volume of approximately 2265 cubic centimeters differs from the actual by 585 cubic centimeters of red cells or approximately 1280 cubic centimeters of whole blood. In this case the patient lost 1200 cubic centimeters of blood more than that actually measured at operation. The major portion of this was postoperative blood loss and occurred within 24 hours after the patient left the table. Clinical evidence supporting this observation was the large amount of bloody drainage postoperatively in the underwater seal drainage bottle. It is significant that even at the end of 5 weeks the red cell volume had not returned to those levels present before operation.

Fig 6 Splachnicectomy, postoperative blood loss, 865 cubic centimeters. Illustrates difference between theoretical and measured red cell volumes on first postoperative day. Difference is 398 cubic centimeters of red cells or 865 cubic centimeters of whole blood.

Figure 5 is the case of a cystectomy with ureteral implantation in the colon. The operative blood loss was 477 cubic centimeters of whole blood with replacement by 1000 cubic centimeters of whole blood at operation plus 500 cubic centimeters in the next 24 hours. The difference between the theoretical and actual red cell volumes was 473 cubic centimeters of red cells or 1070 cubic centimeters of whole blood. In this patient the postoperative loss of approximately 2 pints of whole blood occurred over a period of 4 days. The increase in red cell volume on the second postoperative day is due to transfusion therapy. The recognition and treatment of postoperative blood loss in this patient illustrates the manner in which studies of the nature described in this paper may be used to prevent uncompensated red cell loss.

Figure 6 represents a splachnicectomy where the difference between the theoretical

and actual red cell volumes was 398 cubic centimeters of red cells, a postoperative whole blood loss of approximately 865 cubic centimeters. This patient died on the seventh postoperative day of a massive coronary thrombosis. At autopsy a retropleural collection of blood estimated at 900 to 1000 cubic centimeters was observed by the pathologist. The operation was not attended by unusual blood loss, and hemostasis appeared complete at the time of closure. The major portion of the blood loss measured by the red cell volumes and found post mortem must have occurred, therefore, in the period after the patient left the operating table. According to the red cell volume determinations it occurred in the first 24 hour period. The report of Lord and Hinton offers suggestive evidence that this type of postoperative loss may be a not infrequent occurrence after lumbodorsal splachnicectomy.

Fig 7 Prostatectomy, postoperative blood loss, 500 cubic centimeters. Illustrates difference between theoretical and measured red cell volumes on first postoperative day. Difference is 190 cubic centimeters of red cells or in this case 500 cubic centimeters of whole blood.

Figure 7 illustrates the red cell volume changes following a transurethral prostatic resection. Operative blood loss was 110 cubic centimeters of whole blood. No transfusions were given. The difference between the theoretical and actual red cell volumes was 198 cubic centimeters which represents 500 cubic centimeters of whole blood lost over and above that measured as operative blood loss by the usual methods.

DISCUSSION

Serial red cell volume studies reported in this paper show that the operative blood loss is greater than that measured by older methods, in addition, further blood loss may occur in the postoperative period and exceed the actual operative blood loss by 100 to 200 per cent. The phenomenon of postoperative blood loss receives additional confirmation from the frequent clinical observations of the bloody drainage or thoracentesis fluid in cases undergoing intrathoracic or transthoracic procedures, the guaiac (+) stools after major gastrointestinal resections, the sanguinous drainage in the postoperative urologic case

or from the perineal wound following the Miles procedure as well as autopsy findings in several cases (28). Neither excessive compensatory plasma dilution nor changes in the mean corpuscular volume of the red cell (3, 5, 24) can adequately explain the observed postoperative decreases in red cell volume or hematocrit. Increased or abnormally rapid destruction of transfused cells ordinarily does not occur (7), nor could excessive blood destruction or decreased blood formation be incriminated, for these were ruled out in this series by appropriate studies including icteric indices, bilirubin studies, and reticulocyte counts.

Due to the insidious nature of postoperative blood loss, the clinical signs customarily observed following acute blood loss may be absent. Emerson and Ebert showed that blood pressure and pulse rate need not be related necessarily to the extent of depletion of the blood volume. Similarly in this series, although postoperative blood loss amounted to as much as 1200 cubic centimeters, the concomitant alteration of blood pressure or pulse rate which might have been expected had it

loss been due to acute hemorrhage did not occur

The available evidence suggests a parallelism between uncompensated depletions of the red cell volume and the hematocrit. Figure 8 represents changes in hematocrit observed in five patients with and without major uncompensated blood loss. Serial determinations of the hematocrit value during the preoperative and postoperative periods afford a simple laboratory test for establishing the presence of uncompensated blood loss. Although further definition of the relationship between a decreased hematocrit and the depleted red cell volume is desirable, in our experience if the hematocrit on the third postoperative day was 5 millimeters or more lower than the preoperative hematocrit, uncompensated whole blood loss in excess of 500 cubic centimeters was invariably present. It is to be emphasized that the blood sample must be drawn under standard basal conditions if the hematocrit is to be used as a simple laboratory test in establishing the presence of uncompensated blood loss. Standard basal conditions imply that the patient be fasting, flat in bed for a minimum of 1 hour, and that sampling be accomplished without prolonged venous stasis.

Severe uncompensated depletions of the red cell volume resulting from operation are replaced only over a period of weeks (12, 19, 31, 32). This is in contrast to the rapid restoration of the plasma volume and total circulating protein, which, although not restored immediately following depletion (9, 30, 36) in the adequately hydrated patient, may be restored to or above control values within 1 to 3 days (4, 19). Therefore, since plasma and cells are lost in the same proportion as they are present in the blood at operation, the hematocrit drawn immediately following surgery may be essentially unchanged from the preoperative hematocrit. However, following the restoration of plasma volume the actual red cell loss becomes fully apparent in the hematocrit decrease on the third postoperative day. Large hematocrit decreases at this time serve as a rough index of the extent of depletion of red cell volume.

Reports in the literature (16, 17, 20, 26) on the effects of massive gastrointestinal hem-

Fig 8 Hematocrit differences observed postoperatively in compensated and uncompensated blood loss as studied by the red cell volume method. Note consistent pattern where uncompensated blood loss of 500 cubic centimeters or more is present.

orrhage record changes in the electrocardiogram, the development of cardiac failure, instances of coronary thrombosis and myocardial infarction and transient or persistent amaurosis following acute blood loss. Though much further investigation is required before relating any of these complications directly to uncompensated red cell loss either as complications or sequelae, it may be significant that in specific instances where we have observed major uncompensated red cell loss we have concurrently observed (1) coronary thrombosis and myocardial infarction, (2) vague central nervous system disorders including disorientation, air hunger, and coma, (3) transient amaurosis, (4) oliguria, and (5) unexplained retardation of convalescence.

Because the body unaided cannot repair rapidly severe depletions of the red cell volume the major role of blood replacement therapy

in the postoperative period is to replenish the depleted red cell volume. The surgeon aware of the phenomenon of postoperative red cell loss by attention to changes in the basal hematocrit may recognize and take the steps necessary to replenish the red cell volume depleted through uncompensated operative or postoperative blood loss.

SUMMARY AND CONCLUSIONS

1 Blood loss resulting from various surgical procedures was measured in the same patients by the standard colorimetric and gravimetric methods and compared with results obtained from repeated preoperative and postoperative red cell volumes. Red cell volumes were computed from the plasma volume (T-1824 method) and hematocrit.

2 Operative blood loss measured by the red cell volume method may be considerably higher than that obtained by the classical colorimetric or gravimetric procedures. The reasons for this discrepancy are discussed, and evidence is presented which suggests that the amount of blood removed from the wound at operation may be less than the actual amount of blood lost from the circulation at operation.

3 Observations in postoperative surgical patients are reported which suggest that postoperative blood loss may be an important complication of major surgical procedures. Even though blood lost at operation may be adequately replaced, a further insidious blood loss may occur after operation. This may be considerably larger in amount than the operative loss.

4 Extensive compensatory mechanisms operate in the human to restore a depleted plasma volume. By contrast, the ability of the body to restore a depleted red cell volume is limited. The need for recognizing and correcting a red cell volume depleted through either operative or postoperative red cell loss is emphasized.

5 It is suggested that in the adequately hydrated patient, the hematocrit value on the third postoperative day is a useful index of uncompensated red cell loss and may serve as a guide for replacement therapy.

VAGINAL HYSTERECTOMY

EUGENE A EDWARDS, M D, F A C S, and ROBERT A BEEBE, M D, Chicago, Illinois

THE increasing incidence of vaginal hysterectomies performed at St Luke's Hospital, Chicago, since 1939 warrants an evaluation of the operative procedure and the results obtained

There is considerable variation in the attitude of gynecologists toward vaginal hysterectomy Heaney (5, 6) has stated that vaginal hysterectomy is the operation of choice in his hands for removal of the uterus except in those cases in which it seems impossible to complete because of fixation of the uterus or because of an unusually large tumor TeLinde (8, 9) holds that in uterine prolapse the uterus should be removed vaginally if it is diseased, either completely, or in part as in the Spaulding-Richardson operation For uterine prolapse without uterine disease he prefers the Watkins transposition or a Manchester operation W C Danforth (3) feels that vaginal removal of the uterus for prolapse is preferable to the Manchester operation

MATERIAL

The series reported by us includes 570 vaginal hysterectomies performed at St Luke's Hospital Chicago, from January 1, 1939 to January 1, 1947

PATHOLOGY

Body of the uterus Of the 570 cases, uterine pathology was present in 295, fibromyomas were present in 234 Of these, 198 uteri were the size of a 2 to 2½ month pregnant uterus, 24 were the size of a 3 to 3½ month pregnant uterus, and 12 were the size of a 4 month pregnant uterus Adenomyosis was encountered 33 times as the only pathologic finding and 18 times in association with fibromyomas Endometrial polyps were found in 29 uteri and in 13 they were in association with fibromyomas Pregnancy was present in 6 patients, carcinoma of the endometrium

in 3 cases and sarcoma in a uterine fibroid was diagnosed microscopically in 3 cases

Cervix Early carcinoma of the cervix was encountered once There was no gross evidence of the lesion Small cervical polyps were present in 6 patients

Fallopian tubes Chronic salpingitis with adhesions was present in 3 patients

Ovaries Endometrial cysts were found in 6 patients Corpora lutea, some of which were cystic and as large as 5 centimeters in diameter, were removed in 13 instances Benign serous cystadenomas were present in 4 patients One of the serous cysts was too large to deliver through the vagina and was removed abdominally after completion of the vaginal hysterectomy The others were removed vaginally

Other pelvic pathology Endometriosis was present in 29 patients, cystourethrocele in 405 patients, rectocele in 413, and enterocele in 55 Complete uterine prolapse was present in 69 patients Descensus of varying degree was present in 124 patients

Normal uteri according to microscopic examination There were 242 uteri removed that were diagnosed as normal by the pathology department Associated pelvic pathology, as above, or altered physiology with pelvic symptoms was present in all of these patients in whom the uterus was removed Of the 242 cases, 193 had relaxations of the anterior and posterior vaginal wall and uterine descensus Abnormal uterine bleeding was present in 49 patients as the sole indication for removal of an otherwise normal uterus In an additional 21 patients bleeding was in association with relaxation of the vaginal wall and descensus

Bleeding Abnormal uterine bleeding as the chief symptom or in association with other symptoms was present in 300 patients 115 had menorrhagia, 27 had metrorrhagia, 110 had menometrorrhagia, and 48 had postmenopausal bleeding

Previous surgery Fifty-eight patients had had previous pelvic operations Thirty-nine

From the Department of Obstetrics and Gynecology, St. Luke's Hospital and Northwestern University Medical School Chicago

had been operated upon abdominally. Of these 15 had had uterine suspensions, 8 cesarean sections, 14 ovarian cysts removed, 1 a tubal pregnancy with removal of the affected tube and ovary, and in 1 a tumor of the uterus was removed. Thirty additional patients had had appendectomies. Five of these were associated with peritonitis and adhesions. Nineteen of the 58 patients had been operated upon vaginally, and of these, 17 had had plastic operations on the cervix or vagina, and 2 had had transposition operations.

Associated medical problems. Blood pressure of 150/90 or higher was present in 129 patients. In 12, the systolic pressure was over 200 and in 36, the diastolic was over 100 millimeters mercury. Organic heart disease was present in 29 patients. Two patients had pulmonary tuberculosis and 1 patient had bilateral chronic pyelonephritis. Five patients had a history of previous thrombophlebitis, 1 of whom had had a pulmonary embolism. Obesity was noted in 109 patients.

Operation performed. Repair of the vaginal wall in conjunction with vaginal hysterectomy was done in 450 of the 570 patients. Cystourethrocele and rectocele repair was performed upon 368 patients. Enterocoele repair was done on 55 patients, 45 had rectocele repair only, and 37 had cystourethrocele repair only. The adnexa were removed in part, or *in toto*, in 23 patients. Resection of the ovary was done once. Morcellation of fibromyomas was necessary in 42 instances.

POSTOPERATIVE COMPLICATIONS

Postoperative complications occurred in 95 of the 570 cases in this series. This represents the number of lesions diagnosed. Other patients had slight elevations in temperature and in accordance with the obstetrical standard of morbidity would have to be considered morbid. The accepted standard is a temperature of 100.4 degrees Fahrenheit (oral) on any 2 days postoperatively excluding the first 24 hours. However, in these patients there were no symptoms or findings from which one could make a diagnosis of a morbid state, therefore they are not con-

sidered instances of morbidity by us. Rather, they are within the limits of the usual or average postoperative reaction observed in patients upon whom vaginal hysterectomy with repair procedures have been performed.

Patients ability to void. Of the 405 patients with anterior vaginal wall repair, 26 (7 per cent) had indwelling catheters placed in the urinary bladder. Of the 379 remaining patients, 37 (10 per cent) voided immediately and were not catheterized at all. Two hundred (53 per cent) voided during the 1st postoperative day, 129 (34 per cent) voided between the 1st and 7th postoperative day, and the remaining 13 (3 per cent) voided by the 14th postoperative day. Of the 165 patients without anterior vaginal wall repair, 5 (3 per cent) had indwelling catheters placed in the urinary bladder. Of the remaining 160 patients, 50 (32 per cent) were not catheterized at all, 101 (63 per cent) voided by the 1st postoperative day, and the remaining 9 patients (5 per cent) voided by the 5th postoperative day.

Catheterization. Of the patients with anterior vaginal wall repair, 37 (10 per cent) were not catheterized, 12 (4 per cent) were catheterized on the operative day only, 6 (17 per cent) required catheterization between the 1st and 3rd postoperative day, 9 (25 per cent) were catheterized between the 4th and 7th postoperative day, and 174 (44 per cent) required catheterization between the 8th and 23rd postoperative day. The longest period of catheterization was 23 days in a patient who developed a urinary tract infection. In the group without anterior vaginal wall repair, 50 (32 per cent) were not catheterized, 10 (6 per cent) were catheterized on the operative day only, 58 (35 per cent) were catheterized between the 1st and 3rd postoperative day, 28 (18 per cent) were catheterized between the 4th and 7th postoperative day, and 14 (9 per cent) required catheterization between the 8th and 14th postoperative day.

Indwelling catheters. Postoperative indwelling catheters are not routinely used on our service. However, in 31 patients they were indicated. In five instances the urinary bladder had been entered at the time of

operation (2 with and 3 without anterior vaginal wall repair) In the other cases an indwelling catheter was used to prevent possible trauma to the urethra from intermittent catheterization where the dissection had been extensive or where the urethral meatus was not plainly visible The average length of time the indwelling catheter remained in the urinary bladder was 4 days, and the longest period of time was 14 days Of the 31 patients, 8 (26 per cent) were not catheterized after removal of the indwelling catheter, 7 (23 per cent) required catheterization for 2 days only, 9 (29 per cent) required catheterization from 3 to 7 days after removal of the catheter, and 6 (22 per cent) patients required catheterization from 8 to 10 days after removal of the indwelling catheter One patient required catheterization 16 days after removal of the catheter

Urinary tract infection Our criteria for the diagnosis of cystitis are a catheterized urine specimen containing 20 milligrams of albumin or more and 10 white blood cells per high power field or more on any 2 consecutive days postoperatively Clinical symptoms are usually present Pyelitis is evidenced by clinical extension to the kidney region Forty-nine patients developed urinary tract infection, 42 had cystitis and 7 had pyelitis also Forty-one of the 49 patients had had anterior vaginal wall repair The onset of the symptoms occurred about the 4th postoperative day on an average The symptoms and infection subsided on an average of 8 days after onset The average hospital stay of these patients was 16 days The treatment used was chemotherapy, antibiotics, and general supportive measures In this group of 49 patients, 3 had indwelling catheters in the urinary bladder Of the remaining 46 patients, 5 (11 per cent) voided on the operative day, 11 (24 per cent) voided by the 3rd postoperative day, and 20 (43 per cent) voided by the 7th postoperative day and 10 voided between the 8th and 23rd postoperative day All of these patients required catheterization

Hemorrhage Postoperative hemorrhage occurred in 9 patients The source of bleeding was from vessels in the tissue of the vaginal

vault at the operative site which had not healed by primary union Five of these patients had had no more than the usual postoperative reaction following vaginal hysterectomy Four of the 9 patients had a high febrile course prior to and after the hemorrhage occurred One patient hemorrhaged on the 6th postoperative day, 2 on the 9th, 2 on the 10th, 1 on the 12th, and 1 on the 15th postoperative day Two hemorrhaged on the 18th postoperative day requiring readmission to the hospital Frank hemorrhage was present in 6 patients and moderate bleeding occurred in 3 patients The vaginal vault was resutured in 5 patients, they received chemotherapy and blood transfusion The hospital stay averaged 20 days All of these patients recovered and at no time was their condition critical

Shock Moderately severe shock was present in 4 patients This occurred at the end of difficult surgical procedures in which there was excessive blood loss during the operation All of these patients responded to treatment for shock due to hemorrhage and their condition was stabilized within 6 to 8 hours postoperatively

Thrombophlebitis There was a localized phlebitis in a varicosity of the lower saphenous vein in 1 patient that occurred on the 13th postoperative day This was treated with an ace bandage and the patient was not kept in bed The symptoms subsided in 3 days There was no instance of pulmonary embolism in this series

Infection in the vaginal vault Localized extraperitoneal infection in the submucosal tissues of the vaginal vault was positively diagnosed in 20 patients Spontaneous drainage into the vagina occurred in all of these patients and all had a febrile course until drainage occurred Two had large hematomas but no true pelvic abscess was noted or diagnosed In 5 additional patients presumptive diagnosis of extraperitoneal infection in the vaginal vault was made Drainage did not occur and the temperature elevation was slight

Peritonitis Generalized peritonitis occurred in 4 patients and was preceded by infection in the tissues of the vaginal vault

The patients were discharged from the hospital on the 18th, 24th, 30th, and 42nd postoperative day.

Fistula Two patients developed ureterovaginal fistulas. The first occurred following a vaginal hysterectomy with anterior and posterior vaginal wall repair together with a right salpingo-oophorectomy all of which was performed without difficulty. The postoperative course was uneventful and the patient was discharged on the 9th postoperative day. On the 15th postoperative day, while at home, she noticed a sudden painless discharge of fluid from the vagina. She was readmitted and an attempt to pass a ureteral catheter into the left ureter was unsuccessful. A left ureterovaginal fistula was diagnosed and a left ureterovesical transplant was performed on the 21st postoperative day. The transplant was not successful and 1 month later the left kidney was removed. The patient's recovery was uneventful and at present she is well with no apparent after-effects. The other patient developed a fistula following a vaginal hysterectomy with anterior vaginal wall repair. During the vaginal hysterectomy there was considerable difficulty in obtaining hemostasis in the right broad ligament, the patient went into shock necessitating rapid completion of the surgical procedure. On the 4th postoperative day, she developed acute pain in the right kidney region. An attempt to pass a ureteral catheter into the right ureter was unsuccessful. A diagnosis of obstruction in the right ureter was made due probably, to ligation of the ureter during the surgical procedure. On the 10th postoperative day, a large amount of foul fluid discharged from the vagina. She was discharged on the 21st postoperative day with a right ureterovaginal fistula to be repaired at a later time. Two months later she was readmitted with a right unilateral pyelitis. Following treatment of this a right nephrectomy was performed. The postoperative course was uneventful and the patient is well at the present time.

Follow-up survey Preoperative urinary symptoms were present in 338 patients. In 286 of them anterior vaginal wall repair was performed. Ninety-seven per cent (277) of

the 286 patients were followed postoperatively, most of them for a period of 3 years or longer.

Recurrence of relaxation of vaginal wall Four patients developed recurrent cystocele, rectocele. One patient developed a recurrent enterocele that required repair. One patient had a complete prolapse of the vaginal vault with symptoms. She was followed for 16 months, refused treatment and did not return for further management.

Recurrence of urinary symptoms Stress incontinence was present in 163 patients preoperatively. This symptom was relieved in 156 patients following surgery. Five (3.1 per cent) continued to have incontinence after operative attempt at correction of the lesion. In 2 additional patients stress incontinence had been present since childhood and continued after the operation. Nocturia was present preoperatively in 175 and frequency was present in 186. Four (2 per cent) continued to have nocturia after surgery, and 1 (1.6 per cent) continued to have frequency after surgery.

Mortality There was 1 death in the series. This represents an uncorrected mortality rate of 0.18 per cent. The patient, a 65 year old primipara, who was 11 years postmenopausal was hospitalized because of complete uterine prolapse. The operation performed was vaginal hysterectomy with anterior and posterior vaginal wall repair. On the 4th postoperative day, the patient developed intermittent pain in the epigastrium associated with nausea and vomiting. The pulse rate varied between 120 and 140. The temperature remained between 100 and 101 degrees Fahrenheit. On the 7th postoperative day the abdomen became distended, bowel sounds were absent and a generalized jaundice developed. The usual supportive measures were instituted which included Wangensteen suction, continuous oxygen and cardiac stimulation. The liver and the heart were enlarged and an auricular fibrillation developed. The patient's condition became worse and she expired suddenly on the 9th postoperative day. The diagnosis was cardiac failure and jaundice of undetermined origin. Autopsy permission was denied.

DISCUSSION

Vaginal removal of the uterus with repair of relaxations of the vaginal walls carries with it as low a mortality rate as any of the major surgical procedures in gynecology. In our series of 570 vaginal hysterectomies, the uncorrected mortality rate was 0.18 per cent. Other clinics report similar low mortality figures. In the 2,798 vaginal hysterectomies performed by the staff of the Presbyterian Hospital of Chicago, the mortality rate was 0.21 per cent. Danforth (2) had 1 death in 600 vaginal hysterectomies or 0.16 per cent. A mortality rate of 0.66 per cent occurred in the 305 cases reported by Tyrone and Weed. In a series of 6,800 vaginal hysterectomies in the various clinics, there were 18 deaths. This represents a mortality rate of 0.26 per cent and is an enviable record for any major surgical procedure. The average mortality rate reported in more than 40,000 abdominal hysterectomies over a similar period of time and by comparable operators was 2.4 per cent. It is obvious to us that the two approaches cannot be compared accurately. We realize that many abdominal hysterectomies are of a much more difficult nature and that they could not be performed vaginally. However, when feasible, removal of the uterus through the vagina is much safer than removal through the abdomen because of the lower mortality rate.

Less often encountered causes of death are those resulting from medical complications that were present before the surgical procedure.

The death in our series was of a medical nature, precipitated by the surgical procedure, and it would no doubt have occurred whichever approach had been used. At the time of operation there was no evident medical contraindication to the surgery. The postoperative course was clearly a complication on a medical basis. We do not believe an error in judgment was involved in permitting this patient to be operated upon.

A morbidity study is not a part of this report. Gynecologic morbidity based on temperature records in accordance with obstetrical standards is not significant, is not adequate, and in no way reflects the true

postoperative condition of the patient. This has been brought out in an earlier report by Jones and Doyle as it applies to abdominal hysterectomy. For this reason specific temperature reactions were not studied. Clinical evaluation of the individual patient's general condition is more pertinent in determining her postoperative status than is the presence of an elevated temperature. Temperatures to 101 degrees Fahrenheit or less during the first 3 to 4 postoperative days are quite common and are rarely indicative of a surgical complication. The temperature usually returns to normal by the 5th day.

Patients upon whom vaginal hysterectomies have been performed experience much less postoperative discomfort than do the abdominal cases. The majority of them are comfortable and require very little sedation after the first 36 hours. They have no tender abdominal incision and therefore there is no need for the abdomen to be splinted by the patient in her movements. There is much less trauma in vaginal surgery and there is no need to pack the intestines up under the diaphragm with resulting gas pains from such manipulation. A lighter plane of anesthesia is possible because of this and because relaxation of the tissues is not as necessary in vaginal surgery.

The average hospital stay in this group was 14 days. In the last year of this report it was 12.5 days. Many are able to go home in 8 days and some of them do so.

The most common complication encountered in this series was urinary tract infection. This represents 52 per cent of all complications, and it occurred in 8 per cent of all patients who had vaginal hysterectomy. Infection of the urinary bladder occurred in 41 of 49 patients who had anterior vaginal wall repair. They required repeated catheterizations and therefore were more likely to develop urinary tract infection. The group of patients that developed infection voided just as promptly as those that did not develop infection. However, they required catheterization for a much longer period of time.

Some patients, before operation, have a chronic low grade cystitis from residual urine

that accompanies a cystourethrocele. Others develop infection from repeated catheterization postoperatively. Overdistention of the bladder postoperatively may be a factor in the development of infection. Trauma to the urinary bladder that accompanies the surgical repair of a cystourethrocele may predispose to infection in the bladder. Extraperitoneal infection in the vaginal vault is frequently associated with cystitis. Vesical or ureteral fistulas are always followed by urinary tract infection. Urinary tract infection prolonged the hospital stay 2 days. Three patients had pyelitis develop 1 month after discharge from the hospital and they were readmitted for treatment. All of these patients responded to therapy and did not have disabilities at a later time.

The possibility of cutting or ligating a ureter exists by either route and may not necessarily be restricted to difficult cases. In the instance where it occurred during a difficult case, the thought that injury to the ureter might result was uppermost in the surgeon's mind during the operation. In the other it occurred during an easily accomplished vaginal hysterectomy. The possibility of ureteral injury is greater in those cases with intraligamentous fibromyomas, inflammatory masses and endometriosis. This danger also exists in complete uterine prolapse because the dissection must be extended farther out into the supporting ligaments in order adequately to perform the necessary repair of the hernia, in this way the ureter may be cut or ligated.

The incidence of fatal pulmonary embolism is less following vaginal hysterectomy than it is after abdominal hysterectomy. Erskine and Shures report that in 21,066 gynecologic procedures at Chelsea over a period of 13 years, the incidence of fatal embolism was 1 in 526 abdominal operations or 0.19 per cent. There were 13,061 vaginal procedures with an incidence of 1 fatal pulmonary embolism in 1,088 vaginal operations or 0.092 per cent. In a group of vaginal hysterectomies at various clinics in the United States, there were 3 cases of fatal pulmonary embolism in 7,000 operations. This is 1 in 2,330 or an incidence of 0.042 per cent.

The occurrence of thrombophlebitis is more frequent following abdominal hysterectomy particularly when a patient has a history of previous thrombophlebitis, pulmonary embolism, or both. Such patients are operated upon vaginally with much more safety.

Severe shock resulting from difficult surgical procedures and excessive blood loss may occur no matter which approach is employed. The degree of shock may be minimized by anticipating its onset. The specific causes for excessive blood loss are varied. During the vaginal removal of a uterus the ligatures may occasionally slip and it may be difficult to religate the tissues, similarly the tissues may slip out of the clamp before the ligature is placed. To reduce the occurrence of these mishaps large pedicles are left on cutting the clamped tissues. Adequate hemostasis is the best safeguard against late postoperative hemorrhage.

Operative failures occurred in 10 (1.8 per cent) of the 570 vaginal hysterectomies. In 6 patients there was recurrence of lesions or relaxations as mentioned. In 8 patients there was a continuation of certain preoperative symptoms for which the patient was, in part, operated upon. It is difficult to account for the recurrences of the lesions. In some it is due to poorly developed tissues utilized for the repair. It is possible that failure to do a sufficiently extensive dissection of the enterocele might account for a recurrence of this lesion. The persistence, for 1 or 2 months postoperatively, of stress incontinence, nocturia, or frequency is not unusual. These symptoms subside where correction is obtained. Stress incontinence persisted in 5 patients for more than 3 months after surgery. In 2 patients, not counted with the above 5, stress incontinence persisted but it had been present since childhood and was not due to any lesion that could be corrected surgically. However, cystourethrocele repair was done (in conjunction with vaginal hysterectomy) in the hope that the incontinence might be alleviated, but this did not result. The 5 patients represent a 3 per cent recurrence of stress incontinence.

We have excellent results with vaginal hysterectomy and repair in the treatment of

complete and partial uterine prolapse We feel that the main supporting structures, the uterosacral, the cardinal, and the pubocervical ligaments are more adequately utilized in the repair with the uterus removed In most instances a prolapsed uterus occurs in women who have either had their desired number of children or who are beyond the childbearing age, and the removal of the uterus need not be questioned on this basis Furthermore, vaginal delivery of an infant in a patient who has had a previous vaginal wall repair carries with it the likelihood of the repair breaking down This possibility of pregnancy exists even in those patients nearing the end of their reproductive period This is obviated with removal of the uterus at the time of the repair

All gynecologists are familiar with the poor results frequently obtained in the medical treatment of "functional uterine bleeding" When medical treatment has been unsuccessful and surgery is necessary, hysterectomy is ideally performed by the vaginal route

Endometriosis in its milder forms such as the subperitoneal type that does not result in adhesions may be treated by vaginal hysterectomy However, the other forms of endometriosis that produce adhesions involving the bowel and adnexa are best handled via the abdominal approach

Fibromyomas often can be removed through the vagina Those of larger size are adequately managed by morcellation, thus we have done with tumors as large as a 4 month pregnant uterus The size of the tumor is not as important as is the associated fixation and position of the tumor or its integral parts Subvesical or broad ligament tumors are best removed abdominally

When surgery is necessary in patients with systemic medical disabilities, vaginal hysterectomy where feasible, is the safer procedure This is particularly true in pulmonary conditions such as tuberculosis or bronchiectasis The patients require less total anesthesia since a lighter plane of anesthesia is permissible, and postoperative excursion of the diaphragm (and lungs) is not as limited as it is in abdominal procedures The blood pressure, blood volume, and cardiac function

are not altered as much in the vaginal approach and therefore cardiac patients (organic heart disease, arteriosclerosis, hypertension) tolerate vaginal surgery with a greater margin of safety For this reason the aged patient is more safely operated upon by the vaginal route

Previous abdominal surgery is seldom a contraindication to vaginal hysterectomy Appendectomies that are uncomplicated rarely interfere with vaginal surgery However, complications such as ruptured appendices with peritonitis may cause adhesions that are very apt to increase the difficulty of vaginal hysterectomy Previous gynecologic surgery is not often a contraindication to vaginal surgery It is seldom that adnexal surgery makes a subsequent vaginal hysterectomy difficult and in none in this report was it a factor Previous cesarean sections or plastic procedures on the anterior or posterior vaginal wall may produce fibrous scar tissue and it may be tedious work to find the correct plane of cleavage between the bladder and the uterus It was in 2 such patients who had had previous cesarean sections that the urinary bladder was opened Previous suspension operations on the uterus may result in fixation of the fundus of the uterus or the upper portion of the broad ligaments However, the uterus can usually be brought into view with tension on the cervix and the hysterectomy completed Those cases with marked fixation are best done abdominally Previous transposition operations (Watkins) almost as a rule result in difficult and tedious surgery This is not necessarily a contraindication as it would be difficult surgery if operated upon abdominally In none of the cases in this report was it necessary to open the abdomen because of adhesions or fixation from previous surgery

We feel that vaginal hysterectomy is superior to the Manchester operation in those cases that require repair of the vaginal walls with or without descensus The Manchester operation is reserved for a select small group of patients who are postmenopausal and have cystourethrocele, normal well supported uterus with long cervixes, and who are not good surgical risks The operating time is shorter

(which here is important) and the results in this type of patient have been uniformly excellent

We do not recommend the Manchester operation in younger women because some of them will require subsequent hysterectomy for uterine disease and it frequently results in difficult surgery by either route

Ovarian tumors or cysts are best removed abdominally. The character of the tumor or cyst cannot be determined accurately before operation and it is most undesirable to rupture cysts during an operation with resultant spill of its contents into the peritoneal cavity. If an ovarian tumor or cyst is encountered during a vaginal hysterectomy, unless of small size, the hysterectomy is completed vaginally, and the abdomen is then opened to remove the cyst. There was one instance of this in our report when a serous cyst was encountered and it was removed through the abdomen after the vaginal hysterectomy had been completed.

Cancers of the uterus or adnexa should not be removed vaginally. A much wider and more adequate removal is accomplished abdominally, and in addition, a better evaluation of the extent of the malignant growth is possible. There are occasional exceptions to this policy. A very old patient with carcinoma of the endometrium is more apt to survive a vaginal removal of the uterus.

The clinical evaluation of the individual patient is usually sufficient to rule out the case with a probable carcinoma of the uterus, if not, curettage is an important aid. If question remains, the abdominal route is elected almost as a rule. In an attempt to become more familiar with the curetted endometrium and to avoid such mistakes, 2 members of the staff have routinely curetted all their patients subjected to vaginal hysterectomy since January 1, 1947. A tentative diagnosis is made at the time of the curettement.

During the 8 year period covered in this report, 27.5 per cent of the hysterectomies were performed through the vagina. During 1946, 48.2 per cent were done in this manner. This increase in the number of vaginal hysterectomies is largely due to increasing ex-

perience and this has broadened our indications for vaginal removal of the uterus.

From all of this we have established the following indications and contraindications for use in our private and ward practice, and for teaching purposes.

INDICATIONS

- 1 Lower mortality rate for vaginal hysterectomy and repair than for any other major gynecologic operation
- 2 Lower incidence of postoperative complications
- 3 Associated medical problems more safely managed when vaginal surgery is performed
- 4 Better results achieved in repair of lacerations of the childbirth canal
- 5 Removal of uterine fibromyomas as large as a 4 month pregnant uterus may be accomplished
- 6 "Functional uterine bleeding" not responsive to medical treatment ideally treated by vaginal hysterectomy

CONTRAINDICATIONS

- 1 Cancer of the uterus, tubes, and ovaries
- 2 Ovarian tumors, cysts, or both, unless of small size
- 3 Endometriosis unless of minimal involvement
- 4 Fibromyomas that produce fixation by their position
- 5 Residues of pelvic inflammatory disease

SUMMARY

- 1 An analysis of 570 vaginal hysterectomies is reported
- 2 A mortality rate of 0.18 per cent occurred
- 3 A morbidity study is not a part of this report, more significantly, complications following vaginal hysterectomy are shown and the causes for such if determined
- 4 One-half of the complications encountered were urinary tract infections and of minor nature
- 5 The more serious postoperative complications, in degree of frequency were extraperitoneal infection in the tissues of the vaginal vault, 25, postoperative hemorrhage,

9, moderately severe shock, 4, generalized peritonitis, 4, ureterovaginal fistulas, 2

6 Better results are achieved in the treatment of relaxations of the vaginal walls and uterine descensus

7 Previous gynecologic surgery is not often a contraindication to vaginal hysterectomy

EXPERIMENTAL THORACIC DUCT FISTULA

Observations on the Technique, the Absorption of Fat and Fluid from the Intestine, and Protein Depletion

WILLIAM W L GLENN, M D, New Haven, Connecticut, SAMUEL L CRESSON, M D, FRANCIS X BAUER, M D, FRANZ GOLDSTEIN, OLIVE HOFFMAN, Ph D, M D, and JOHN E HEALEY, Jr, M D, Philadelphia, Pennsylvania

THE purpose of this paper is to describe a technique whereby a thoracic duct fistula, which will drain freely for a number of days, may be established in the dog. In addition, an attempt was made to determine how completely the lymph, drained by the thoracic duct, was excluded from the blood following the production of such a fistula. Observations were made on the absorption of fat and fluid from the intestine, and changes in the concentration of protein in lymph and serum were recorded.

THE PROBLEM

Lymph fistulas in man, following neoplastic invasion and traumatic or operative injury to the thoracic duct and larger lymph channels, are not uncommon (5, 8, 11, 15, 17, 23, 25, 26). The loss of lymph rich in protein and fat in these patients may reach enormous proportions and, if uncorrected, may have disastrous consequences. The fact that lymph fistulas develop and persist in man is in striking contrast to the difficulty encountered in the deliberate attempt to create such fistulas in animals. Until recently, efforts to produce in dogs thoracic duct fistulas, which will drain freely for more than a few hours, have been unsuccessful.

The principal difficulty encountered has been the clotting of lymph in the thoracic duct cannula. In survival experiments, the usefulness of anticoagulants is limited. Heparin applied locally in the cannula is efficient in experiments of short duration but is not practical over long periods. The prolongation of the blood coagulation is difficult to control when either heparin or dicoumarin is administered

systematically to the dog. Using dicoumarin we were unable to maintain a prothrombin level in the blood sufficiently low to prevent coagulation of the lymph in a glass cannula without endangering the life of the animal. Doses of dicoumarin of 2 milligrams per kilogram body weight daily for 3 to 6 days resulted frequently in fatal hemorrhages from the gastrointestinal tract.

A second and more successful approach to the problem of preventing coagulation of the lymph is the use of thoracic duct cannulas in which coagulation is delayed.

Zimmermann and Meyers in 1945 called attention to the delayed clotting of blood in contact with the plastic polyethylene. They demonstrated that fine tubing of this material could be used to replace the conventional intravenous needle in cases in which prolonged intravenous therapy was given.

Cain and his co-workers (6) were the first to report successful thoracic duct fistulas in dogs of 4 to 8 days' duration. These authors used small tubing of polyvinyl chloride inserted into the lower thoracic duct through a transpleural approach. In approximately one-third of their experiments they reported successful cannulations suitable for study.

In our work cannulas made from polyethylene tubing have been employed for direct cannulation of the thoracic duct in the neck. These cannulas can be made easily in a few moments over a small flame (Fig 1).

TECHNIQUE

The technique consists of the following steps:

First, under nembutal anesthesia the right lymphatic duct and the right cervical duct are ligated and divided, as are also the

From the Department of Surgical Research, Jefferson Medical College, Philadelphia, Pennsylvania.

visible lymphatic connections between the right and left sides, and to the great veins in the mediastinum down to the pericardium. This procedure can usually be carried out without entering the pleura through a 2 inch transverse incision just above the medial portion of the right first rib. Freeman has clearly demonstrated in the dog that intestinal lymph may empty into the blood through channels other than the thoracic duct-venous junction in the neck. He found accessory connections between the thoracic duct and the right duct and between the thoracic duct and the azygos vein in the thorax. He states that such accessory connections are the rule rather than the exception. Other accessory connections are probably present in the abdomen (2). Ligation of the right duct and clearing of the superior vena cava down to the pericardium and the upper part of the azygos vein are important steps in eliminating a major group of these recognized accessory connections.

Second, 1 or 2 weeks later, after the animal has fully recovered from the first operation, the thoracic duct is cannulated under 1 per cent procaine infiltration anesthesia. The cannulation of the thoracic duct in the neck under local anesthesia, not a new (19) nor a difficult procedure, is preferable for several reasons. The general bodily changes incident to a more formidable procedure or to a general anesthesia are not encountered. Also, studies upon the ambulatory dogs can be started at once, an important consideration in an animal which is losing large amounts of fluid, fat, protein, and electrolytes through a thoracic duct fistula.

In the dog, the thoracic duct or frequently the largest branch, if there are several, empties into a lymphatic ampulla which also receives the termination of the left subclavian duct and the left cervical duct. The ampulla lies just behind the lower end of the jugular vein and empties into the blood stream by way of two ducts, one passing on either side of the jugular vein. The one passing laterally enters the blood stream at the junction of the jugular vein with the subclavian vein, the other passing medially enters the blood stream at the junction of the jugular vein with the innominate vein. The ampulla can usually be easily

Fig 1

identified after the jugular vein is retracted laterally. The cervical duct, the left subclavian duct, and the two terminal branches of the ampulla are identified and tied off. The ampulla, with its exits to the blood thus closed, becomes distended with thoracic duct lymph. Careful dissection will reveal a distended thoracic duct coming up from below and behind the ampulla. With care being taken not to injure the duct or the immediate perilymphatic tissue, a ligature is placed, but not tied, around the thoracic duct just below the ampulla. The ampulla is then incised and the thoracic duct opening into the ampulla can be clearly seen as the lymph pours forth. A polyethylene cannula of suitable size is slipped into the opening and secured with the previously placed ligature. In this way, little damage is done to the thoracic duct distal to the cannula. Also the ampulla, fixed as it is to the surrounding tissues, makes twisting or kinking of the thoracic duct unlikely. Minor variations in the anatomical arrangement of the lymphatic terminal on the left side are common, and branches of the thoracic duct emptying either separately into the ampulla or directly into the veins should be searched for and tied. Several attempts were made to thread a polyethylene tube of small diameter distally into the thoracic duct. This was prevented after a short distance by the presence of valves which could be easily demonstrated after the duct was removed.

Third, the animal is placed on its feet and a plaster cast is applied from the midthorax to the angle of the jaw. A window is left for the projection of the cannula and ample openings are provided for both forelegs to allow free locomotion. The cast is an essential part of this technique. The animal can walk, sit, or lie in comfort but is prevented from moving

EXPERIMENTAL THORACIC DUCT FISTULA

Observations on the Technique, the Absorption of Fat and Fluid from the Intestine, and Protein Depletion

WILLIAM W L GLENN, M D, New Haven, Connecticut, SAMUEL L CRESSON, M D, FRANCIS X BAUER, M D, FRANZ GOLDSTEIN, OLIVE HOFFMAN, Ph D, M D, and JOHN E HEALEY, Jr, M D, Philadelphia, Pennsylvania

THE purpose of this paper is to describe a technique whereby a thoracic duct fistula, which will drain freely for a number of days, may be established in the dog. In addition, an attempt was made to determine how completely the lymph, drained by the thoracic duct, was excluded from the blood following the production of such a fistula. Observations were made on the absorption of fat and fluid from the intestine, and changes in the concentration of protein in lymph and serum were recorded.

THE PROBLEM

Lymph fistulas in man, following neoplastic invasion and traumatic or operative injury to the thoracic duct and larger lymph channels, are not uncommon (5, 8, 11, 15, 17, 23, 25, 26). The loss of lymph rich in protein and fat in these patients may reach enormous proportions and, if uncorrected, may have disastrous consequences. The fact that lymph fistulas develop and persist in man is in striking contrast to the difficulty encountered in the deliberate attempt to create such fistulas in animals. Until recently, efforts to produce in dogs thoracic duct fistulas, which will drain freely for more than a few hours, have been unsuccessful.

The principal difficulty encountered has been the clotting of lymph in the thoracic duct cannula. In survival experiments, the usefulness of anticoagulants is limited. Heparin applied locally in the cannula is efficient in experiments of short duration but is not practical over long periods. The prolongation of the blood coagulation is difficult to control when either heparin or dicoumarin is administered

systematically to the dog. Using dicoumarin, we were unable to maintain a prothrombin level in the blood sufficiently low to prevent coagulation of the lymph in a glass cannula without endangering the life of the animal. Doses of dicoumarin of 2 milligrams per kilogram body weight daily for 3 to 6 days resulted frequently in fatal hemorrhages from the gastrointestinal tract.

A second and more successful approach to the problem of preventing coagulation of the lymph is the use of thoracic duct cannulas in which coagulation is delayed.

Zimmermann and Meyers in 1945 called attention to the delayed clotting of blood in contact with the plastic polyethylene. They demonstrated that fine tubing of this material could be used to replace the conventional intravenous needle in cases in which prolonged intravenous therapy was given.

Cam and his co-workers (6) were the first to report successful thoracic duct fistulas in dogs of 4 to 8 days' duration. These authors used small tubing of polyvinyl chloride inserted into the lower thoracic duct through a transpleural approach. In approximately one-third of their experiments they reported successful cannulations suitable for study.

In our work cannulas made from polyethylene tubing have been employed for direct cannulation of the thoracic duct in the neck. These cannulas can be made easily in a few moments over a small flame (Fig 1).

TECHNIQUE

The technique consists of the following steps:

First, under nembutal anesthesia, the right lymphatic duct and the right cervical duct are ligated and divided, as are also all

visible lymphatic connections between the right and left sides, and to the great veins in the mediastinum down to the pericardium. This procedure can usually be carried out without entering the pleura through a 2 inch transverse incision just above the medial portion of the right first rib. Freeman has clearly demonstrated in the dog that intestinal lymph may empty into the blood through channels other than the thoracic duct-venous junction in the neck. He found accessory connections between the thoracic duct and the right duct and between the thoracic duct and the azygos vein in the thorax. He states that such accessory connections are the rule rather than the exception. Other accessory connections are probably present in the abdomen (2). Ligation of the right duct and clearing of the superior vena cava down to the pericardium and the upper part of the azygos vein are important steps in eliminating a major group of these recognized accessory connections.

Second, 1 or 2 weeks later, after the animal has fully recovered from the first operation, the thoracic duct is cannulated under 1 per cent procaine infiltration anesthesia. The cannulation of the thoracic duct in the neck under local anesthesia, not a new (19) nor a difficult procedure, is preferable for several reasons. The general bodily changes incident to a more formidable procedure or to a general anesthesia are not encountered. Also, studies upon the ambulatory dogs can be started at once, an important consideration in an animal which is losing large amounts of fluid, fat, protein, and electrolytes through a thoracic duct fistula.

In the dog, the thoracic duct or frequently the largest branch, if there are several, empties into a lymphatic ampulla which also receives the termination of the left subclavian duct and the left cervical duct. The ampulla lies just behind the lower end of the jugular vein and empties into the blood stream by way of two ducts, one passing on either side of the jugular vein. The one passing laterally enters the blood stream at the junction of the jugular vein with the subclavian vein, the other passing medially enters the blood stream at the junction of the jugular vein with the innominate vein. The ampulla can usually be easily

Fig 1

identified after the jugular vein is retracted laterally. The cervical duct, the left subclavian duct, and the two terminal branches of the ampulla are identified and tied off. The ampulla, with its exits to the blood thus closed, becomes distended with thoracic duct lymph. Careful dissection will reveal a distended thoracic duct coming up from below and behind the ampulla. With care being taken not to injure the duct or the immediate perilymphatic tissue, a ligature is placed, but not tied, around the thoracic duct just below the ampulla. The ampulla is then incised and the thoracic duct opening into the ampulla can be clearly seen as the lymph pours forth. A polyethylene cannula of suitable size is slipped into the opening and secured with the previously placed ligature. In this way, little damage is done to the thoracic duct distal to the cannula. Also the ampulla, fixed as it is to the surrounding tissues, makes twisting or kinking of the thoracic duct unlikely. Minor variations in the anatomical arrangement of the lymphatic terminal on the left side are common, and branches of the thoracic duct emptying either separately into the ampulla or directly into the veins should be searched for and tied. Several attempts were made to thread a polyethylene tube of small diameter distally into the thoracic duct. This was prevented after a short distance by the presence of valves which could be easily demonstrated after the duct was removed.

Third, the animal is placed on its feet and a plaster cast is applied from the midthorax to the angle of the jaw. A window is left for the projection of the cannula and ample openings are provided for both forelegs to allow free locomotion. The cast is an essential part of this technique. The animal can walk, sit, or lie in comfort but is prevented from moving

his neck and thus interfering with the position of the cannula. The cast should not be applied with the animal under general anesthesia, as a proper fitting for the plaster under these conditions is almost impossible.

If it is desired, 4 to 6 inches of a 12 to 18 inch segment of small polyethylene tubing can be inserted through a large needle into the right jugular vein (21) prior to the application of the plaster. The rest of the tubing is then brought out through the plaster. Into the open end of the polyethylene tube can be inserted a small needle tied onto the end of a segment of latex tubing distended with 300 to 500 cubic centimeters of fluid which is allowed to run in slowly, as suggested by Zinsser and Parkins. The distended latex tubing can be carried on a cannister strapped to the plaster on the animal's back.

Thirteen experiments using this technique have been carried out. Five were unsuccessful. The most frequent cause of failure was multiple branching of the thoracic duct at the point of termination in the neck. This cause of failure should become less, however, as experience with the technique is gained. Whereas there were 3 failures in the first 7 experiments due to this, there was only 1 failure in the last 6 from this cause or any other. The 1 other failure, also in the first 7 experiments, was due to the dog's becoming so restless that it was necessary to abandon the procedure under local anesthesia.

Six of the 8 successful cannulations drained freely from 4 to 8 days. Of the other 2, one cannula was pulled out deliberately on the third day of drainage as the contemplated studies had been completed, in the other, the cannula was accidentally removed while being cleaned on the third day of drainage. Occasionally, small clots form in the cannulas. These can be extracted usually by means of a twisting motion with a small wire in the lumen of the cannula. During the period of fistula drainage the animals were usually docile and cooperative. In 1 experiment however sedative doses of pentothal sodium were required.

ACCESSORY LYMPHATICOVENOUS CONNECTIONS

To evaluate studies on an animal with a freely draining thoracic duct fistula, it is im-

portant to determine whether collateral lymphaticovenous connections are functioning.

Method. Within 1 hour of the creation of a freely draining thoracic duct fistula in 7 dogs, 2 cubic centimeters of a 1 per cent solution of the colloidal dye T-1824 were injected cephalad into a cannulated lymphatic on the dorsum of one hind foot. A second injection into the lymphatic on the dorsum of the opposite hind foot, was carried out after the fistula had closed some time later. In all but 1, the solute for the T-1824 was the dog's own serum. In 5 experiments, the 2 injections were performed under local anesthesia. In the other 2 experiments, nembutal anesthesia was used. The appearance time of the dye was noted in the lymph flowing from the thoracic duct cannula following the first injection. Following both injections, samples of venous blood were obtained at intervals of 3 minutes to 30 minutes after the dye was injected into the lymphatic. The presence of dye in the serum was determined by either the Beckman spectrophotometer or by the Evelyn photoelectric colorimeter.

Results. The appearance time of the T-1824 in the lymph, flowing from the thoracic duct cannula after injection of the dye into a hind foot lymphatic, varied between 30 seconds and 5 minutes and 50 seconds with an average for the 7 experiments of 2 minutes and 30 seconds.

With a freely draining thoracic duct fistula a small amount of dye was detected in the serum within 15 minutes after the dye was injected into the peripheral lymphatic in all but 1 of these control experiments. It may be of significance that in the 1 experiment in which no dye appeared in the blood, the animal was under a general anesthetic.

A lymphatic on the dorsum of the opposite hind foot was injected in an exactly similar manner after the thoracic duct fistula closed. In every case the amount of dye found in the blood serum following the closure of the thoracic duct fistula was greater than that found when the lymph was flowing unimpeded through the fistula.

It is evident that even with a freely draining thoracic duct fistula in the dog, a colloidal dye of large molecular size passes from the lymphatic to blood stream somewhere between

the hind foot and the neck in the majority of animals. The amount of dye that reaches the blood in a freely draining fistula is extremely small but the blood concentration increases almost immediately if the thoracic duct is obstructed in the neck.

There is some question as to where the colloidal dye T-1824 passes from lymphatic to blood vessel. It is possible that some of the dye diffused through the blood capillary wall directly. The most likely site for this to occur would appear to be the lymph nodes. Although the colloidal dye T-1824 passes slowly from the blood stream into the tissues (13), it has not been demonstrated that this substance or the albumen to which it becomes attached passes through the capillary wall in the opposite direction. In view of the demonstration by several investigators (2, 16) of accessory lymphaticovenous connections in the dog, it seems unnecessary to postulate the diffusion of the dye through the capillary wall. The injection of a dye into a peripheral lymphatic gives no information as to possible connections between the mesenteric lymphatics and the mesenteric veins.

FAT ABSORPTION STUDY

Thoracic duct fistulas of short duration have been utilized for many years in the study of the absorption of fat from the intestine. There remains some doubt as to whether fat is absorbed solely by way of the lymphatics or whether some of it may pass directly into the portal blood. Until recently (7), general anesthesia has been employed in these studies. Also, precautions have not been taken to block the entrance of thoracic duct lymph into the blood through the right duct. The possibility that these factors may be of importance has, however, been recognized for some time (10).

Method Fat was determined as total lipid fatty acids in the lymph and serum, according to the method of Bloor (4). Partitioning of the fatty acids was not done. In several of the earlier experiments, specimens of blood were taken for analysis from 1 to 12 hours after the administration of fat. It was found that maximum lipemia occurred usually about the fifth hour following the administration by

stomach tube of 4 cubic centimeters of olive oil per kilogram of body weight. Total lipid fatty acids were determined simultaneously on the serum and lymph following the creation of the thoracic duct fistulas. The determinations were made before the administration of olive oil and on specimens taken 3 and 5 hours, and occasionally at 2 and 7 hours, after the administration of oil. In 5 healthy dogs, prefistula fat absorption studies were made approximately 1 week before the fistulas were established. Similar studies were carried out immediately following the cannulation of the thoracic duct under local anesthesia. In 3 experiments, a fat absorption study was also made on the eighth, eighteenth, and thirty-second day respectively, after the thoracic duct fistulas had closed. The animals were starved for at least 24 hours prior to each fat absorption study.

Results The results of this study in 5 animals are recorded in Table I. With a freely draining thoracic duct fistula, no appreciable increase in the serum lipids is evident at the time of maximum fat absorption, as judged by the level of the total lipid fatty acids in the lymph. It is possible that small amounts of absorbed fat may have reached the blood stream, either through the portal blood or through accessory lymphaticovenous connections. Small increments in the total lipid fatty acids cannot be determined reliably by chemical methods (3). The presence of functioning

lymphaticovenous connections, other than the thoracic duct or the right duct, is evident from the fat absorption studies carried out after the thoracic duct fistulas had closed

With sucrose or glucose as the only source of food, a definite increase in the opalescence of the thoracic duct lymph was noted following the administration of fluid by mouth up to 7 days after any fat was given by mouth. This was coincident with an increase in lymph flow. These changes were observed to occur within 10 to 30 minutes after fluid was given and continued for 2 to 3 hours. If more fluid was given after 2 to 3 hours, or after several days, this phenomenon was repeated. The increase in the opalescence was most marked in the first 30 to 60 minutes after fluid administration and became progressively less as the lymph flow continued to increase. The initial increase in the opalescence was less evident as the administration of large amounts of fluid was repeated frequently. Determination of the total lipid fatty acids in the lymph, soon after the opalescence appeared to increase grossly, revealed an increase in the fat content. The results of such a study are recorded in Table II. This dog had received no food for 72 hours prior to the creation of the thoracic duct fistula. The study was made 22 hours after the fistula was established during which time the dog received by vein about 1600 cubic centimeters of 5 per cent dextrose in water and 1600 cubic centimeters of 5 per cent dextrose in 0.85 per cent saline. No olive oil had been given. The increase in the fat content of the lymph in this dog was somewhat more marked than usual. However, no fluid had been taken by mouth for 24 hours prior to this study. The type of fluid given, whether it was water with or without glucose

or saline, did not appear to make any difference in the degree of opalescence. However, as almost all of the animals were given a large amount of glucose, from which fat may have been formed (1), during the course of fistula drainage, it was not determined whether absolute starvation would elicit a greater or smaller increase in the opalescence of the lymph following fluid by mouth.

The rapid increase in the fat content of the lymph following the administration of fluid by mouth suggests that the fat lay within the lumen of the lacteals and that it was washed up by the absorption of some of the ingested fluid. It gives no clue, however, as to how the fat came to be in the intestinal lacteals or the mechanism involved in the replacement by more fat between periods of fluid administration. The experiments of Roney, Mortimer, and Ivy are interesting in this regard. They found high lipid levels in the thoracic duct lymph in dogs starved for 2 to 14 days, following enterectomy, however, no such increases were observed. They concluded that fat mobilized during starvation was transported to the intestinal mucosa where it was secreted into the intestine, the major portion being reabsorbed and passed into the lacteals.

PROTEIN STUDY

The protein concentration of the thoracic duct lymph in the dog averages 3 to 4 grams per cent (9). This is considerably higher than the concentration of protein in peripheral lymph. The difference is due to the large contribution of protein made by liver lymph (14). It is of interest to know whether there is a parallel fall of the serum protein concentration and the thoracic duct lymph protein concentration following the loss of large amounts of protein through a thoracic duct fistula.

Method. In 6 healthy dogs, protein determinations were made daily on the serum and lymph during the period of fistula drainage. A few of the early determinations were done by the copper sulfate method of Phillips and co-workers. This method was found unsatisfactory for some specimens of the thoracic duct lymph, apparently because of a lowering of the specific gravity of the lymph incident to the high fat content. The micro-Kjeldahl

method was used in all subsequent determinations. In 2 of the experiments, 4 and 8, the last protein determinations were made on the day prior to closure of the fistulas. An attempt was made to obtain specimens of blood and lymph at the same time each day, usually in the early morning before fluid administration was begun. Variations in the lymph flow between the daily samples could not be avoided. Except in experiment 2 (Fig. 3), in which a deliberate attempt was made to obtain a maximum flow of lymph, these variations were usually not great, but may have accounted for some of the irregularities in the lymph protein concentration.

Results. A progressive fall in both the serum protein concentration and the lymph protein concentration was found. The control determinations and the last determinations made while the fistulas were still draining are recorded in Table III. The loss of protein was greater than is evident from these findings, however, as in every case some degree of hemoconcentration developed. It is apparent that the loss of protein through a thoracic duct fistula in the presence of a protein free diet, in the course of a few days will markedly reduce the serum protein concentration. Clinically, Crandall, Barker and Graham have found the loss of protein in the lymph draining from a thoracic duct fistula to be a major therapeutic consideration.

FLUID ABSORPTION STUDY

A distinct difference in the thoracic duct lymph flow was observed in some of the earlier experiments following the prolonged administration by mouth of 5 per cent glucose in 0.6 or 0.85 per cent saline solution and 5 per cent glucose in distilled water. The ingestion of smaller amounts of these solutions did not, however, reveal appreciable differences in the volume of thoracic duct lymph flow. With a thoracic duct fistula of several days duration, an opportunity is afforded to make observations on the variation in lymph flow following the prolonged administration of either or both of these fluids.

Method. Four experiments were performed. These were divided into two groups with 2 experiments in each group. The first group

Fluids by vein were administered continuously, and there was no interval between the two fluid periods.

Results In all of the experiments, saline solution produced a sustained and continued increase in lymph flow with a low urinary output. The prolonged administration of

Fig 2

water was accompanied by a moderate initial increase in lymph flow, and a relative diuresis. In Figure 2, the thoracic duct lymph flow is recorded graphically in one of the experiments in which fluids were given by mouth. The animal was initially hypoproteinemic (not included in the normal series, Table III). Two thousand cubic centimeters of 5 per cent dextrose in water was given on the second day of fistula drainage and a like amount of 5 per cent dextrose in 0.85 per cent saline solution was given on the third day of fistula drainage. The serum protein concentration at the start of the dextrose in water was 3.15 grams per cent and on the following day at the start of dextrose in saline was 3.87 grams per cent. The values recorded are the average amounts of lymph drained per minute over successive 2 hour periods. The increase in lymph flow when saline solution was administered by mouth was much greater than when saline

solution was administered by vein. In the 2 animals receiving saline solution by vein, gross peripheral edema became evident. However, edema was moderate or absent in the animals receiving saline solution by mouth. In an earlier experiment (Fig 4) not included in this series, approximately 15 liters of 0.6 per cent saline, most of it with 10 per cent sucrose, was given by mouth to a 21 kilogram dog over a period of 4 days. The estimated lymph flow, based on interval collections made over a 16 to 18 hour period daily, almost equalled the fluid intake. The lymph flow stopped on the fifth day of drainage when the cannula fell out. Persistent edema in this animal was evident only at the site of the operative wounds. The estimated total amount of lymph drained, and the duration of saline administration was greater in this dog than in any other. This experiment is cited principally to show the maximum lymph flow ob-

Fig 3

tained. It is not intended to imply that all or even a major portion of the saline solution given by mouth was absorbed into the intestinal lacteals. Other factors, such as the fact that this animal was unusually active (28), undoubtedly contributed to the maximal flow of lymph.

The difference in the thoracic duct lymph flow accompanying the administration of saline solution by mouth and water by mouth may be explained in the following manner. The moderate lymph flow that accompanied the prolonged administration of water would indicate that water was, for the most part, absorbed directly into the blood. On the other hand, relatively more of the saline solution administered in the same manner appeared to pass into the tissue spaces of the intestinal wall where it was forced into and along the adjacent lacteals by the continuous propulsive force of intestinal peristalsis. Saline so-

lution administered intravenously accumulated in the loose subcutaneous tissue where no such involuntary propulsive muscular activity exists. One must consider the fact that during the periods of fluid administration the transudation of saline into the interstitial spaces was enhanced by the invariable fall in serum protein concentration observed in these animals (12, 24, 27).

SUMMARY

1 Thoracic duct fistulas which drained freely for a number of days have been established in 8 dogs. The thoracic duct was cannulated in the neck under local anesthesia with a cannula made from polyethylene tubing.

2 From the studies carried out with the dye T-1824, it seems probable that an abundance of accessory lymphaticovenous connections exist and that they are, as Freeman says, the rule rather than the exception. It is im-

portant, therefore, that in the interpretation of experimental data with a thoracic duct fistula, one considers the possible functional significance of these accessory connections

3 In the presence of a thoracic duct fistula, the administration of olive oil by stomach tube did not cause an appreciable rise in the total lipid fatty acids in the serum at the time of maximum fat absorption as judged by the lipid content of the thoracic duct lymph. This does not mean, however, that fat may not have reached the blood through direct portal vein absorption or through accessory lymphaticovenous connections. It only indicates that in the presence of an unobstructed thoracic duct, the absorption of fats by any other route must be small.

There was an increase in the lipid content of thoracic duct lymph following the administration of fluids by mouth to dogs whose only source of food was glucose or sucrose. The experiments suggested that fat was being continuously replaced in the intestinal lacteals. The mechanism of this replacement was not determined.

4 There was a progressive loss of protein through the thoracic duct fistula. This resulted in a rapid fall in the protein concentration of both lymph and blood. In general, the fall in serum protein concentration paralleled the fall in lymph protein concentration.

5 Glucose in saline solution by mouth resulted in a greater increase in thoracic duct lymph flow than did glucose in water by mouth, or glucose in saline solution or water by vein. Some of the factors of importance in the interpretation of these observations are the propulsive force of intestinal peristalsis, depletion of serum proteins, different rates of excretion of these fluids by the kidneys.

EWING'S TUMOR

BARTON McSWAIN, M D, F A C S, BENJAMIN F BYRD, JR, M D, and
W O INMAN, JR, M D, Nashville, Tennessee

THE purpose of this article is primarily to report the apparent cures of 3 patients with Ewing's tumor of bone (in one of whom there was disappearance, without direct treatment, of an apparent pulmonary metastasis), and secondarily to summarize the features of all cases of Ewing's tumor which have been seen at the Vanderbilt University Hospital since 1925

INCIDENCE

General Since 1925 there have been 192 specimens of bone tumors, exclusive of metastases, submitted to the Surgical Pathology Laboratory, of which 71 were malignant. The 20 Ewing's tumors found in this series thus represent an incidence of 10 per cent of all bone tumors and 28 per cent of malignant bone tumors

Race Geschickter and Copeland (35) noted the occurrence of Ewing's tumor in only 1 negro in a total of 122 patients with such tumors, whereas 2 of our 20 patients were negroes

Sex Like other observers (35), we found that Ewing's tumors are more frequent in males, there having been 13 males and 7 females

Age The youngest patient was 3 and the eldest 43 years of age. There were 5 patients in the first decade, 9 in the second, 3 in the third, 1 in the fourth, and 2 in the fifth. The occurrence of Ewing's tumors in patients over 40 years of age is unusual, but Geschickter and Copeland (35) reported 2 such cases in patients 44 years of age, and Stout (87) stated that "the age variation extends from 4 to 79 years." Eighty per cent of our patients were less than 25 years of age

Site (Table I) In contradistinction to the findings of Ewing (32) and Geschickter and Copeland (35), but like Stout (87) and Lich-

tenstein and Jaffe (61) we found the tumors more frequently in flat bones (14 cases) than in long bones (6 cases). Five of the tumors of the long bones originated in the diaphysis, only 1 of these 5 having arisen in the region of the metaphysis. In the sixth patient the roentgenogram of the femur showed involvement of both the metaphysis and the epiphysis so that it was impossible to state the exact site of origin of the tumor

SUBJECTIVE MANIFESTATIONS

Duration of symptoms The periods which had elapsed from the onset of symptoms until the application to this clinic for treatment ranged from 5 weeks to 12 months, the average time having been 5 months for all patients and slightly less than 5 months for the individuals who died. The patients still alive had had symptoms for 4, 4, and 10 months, respectively

Injury The question as to whether injury may be a factor in causing a bone tumor or whether it simply calls attention to an area in which the lesion is already present has never been settled. However, in instances in which a tumor occurs at a site which, a few weeks before, was subjected to a severe blow one hesitates to deny the possibility of such trauma as an etiologic agent. In 10 patients there was no injury, while in each of the other 10 there was a definite history of a severe injury, however in 1 patient injury occurred 25 years before admission. In 1 instance, the interval between injury and swelling was not recorded and in another it was stated to have been "several weeks." In 2 individuals pain occurred at the time of the injury and did not subside, the swelling having been noted 3 days later in 1 patient (Case 2) and 2 months later in the other. In the 5 remaining patients the injury preceded the occurrence of pain or swelling by intervals of 1 week, 1 month, 2 months, 10 months, and 10 months

Fig 1 The roentgenogram of the scapula shows new bone formation in the so-called "sunray" fashion which is often considered highly suggestive of osteogenic sarcoma. Microscopic section of the tissue removed at exploration showed Ewing's tumor.

Pain The occurrence of pain was recorded in all instances except that of a child with a tumor of the scapula, who was brought to the hospital because his parents noted the presence of a mass.

Swelling Swelling was noted by the patient or his family in all instances except 1 in which the tumor was in the twelfth rib. In 10 patients there had been a slow increase in size, in 4 the increase had been rapid, in 1 patient there had been no change since the mass was first noticed (9 weeks before admission to the hospital), and in 1 patient the presence or absence of this symptom was not recorded. There was a definite history of fluctuation in the size of the tumor in each of 3 individuals. One patient developed a swelling which subsided completely and then recurred and persisted until time of admission to this clinic. In 2 patients the swelling occurred, subsided completely, recurred and subsided, and again recurred and subsided before the third recurrence which failed to regress before treatment.

Fracture A spontaneous fracture occurred in only 1 instance, the patient having fractured the shaft of the femur 15 months after injury and 5 months after the appearance of the tumor.

PHYSICAL AND LABORATORY FINDINGS

Evidence of inflammatory disease There was some evidence of inflammatory disease in all patients. Every individual had an elevation of temperature before operation to 99 degrees F or more. In each of 14 patients there was a rise in temperature before operation to 100 degrees or more, the maximum temperature in any patient having been 103 degrees. In 15 patients there was tenderness over the involved area. In 9 instances it was noted that the skin over the tumor was warmer than it was elsewhere, in 1 instance there was a statement that the skin was not warmer, and in 10 patients the presence or absence of this sign was not recorded. The minimum leukocyte count was 5,200 and the maximum was 18,000. In 10 patients the white blood cell count was 10,000 or more. The evidence of inflammatory disease was so striking that, before admission, aspiration had been done in 1 instance and incision and drainage in another and in the clinic incision and drainage were done in 1 patient.

Characteristics of the tumor In most instances the tumors were visible and in 23 patients they were palpable. Most of the tumors were smooth and all of them were firm or hard, and immovable. Although none was fixed to the skin, one (a tumor of the mu-

¹One patient with a tumor of the scapula did not have a preoperative roentgenogram because the diagnosis was thought to be acute osteomyelitis. Another patient with a tumor of the twelfth rib had a preoperative roentgenogram elsewhere before admission to the Vanderbilt University Hospital. Therefore there is a discrepancy in the totals.

ble) was ulcerated, having been incised before admission

Erythrocyte count In 4 patients the erythrocyte count was below 4 million and in 7 it was below 4.5 million. The range in the other individuals was from 4.5 to 5.5 million. The minimum count was 2.7 million, the maximum 5.5 million.

ROENTGENOLOGIC FINDINGS

The roentgenologic findings (Table II) in our patients were so variable that the diagnosis of Ewing's tumor was made by the roentgenologist in only 5 of the cases which occurred in the flat bones and in none of those which occurred in the long bones. In the patients with tumors of the flat bones the changes were thought to be due to tumor or inflammation in 2 instances and to inflammation in 1 instance. The changes in 2 of the tumors of long bones were thought to be due to osteomyelitis. In 1 instance the so called "sunray" picture (Fig 1) was seen and in another patient the characteristic roentgenologic findings of a bone cyst (Figs 2 and 3) in the twelfth rib were observed. In 1 instance in this clinic the fairly characteristic "onion-peel" appearance has been seen in a bone lesion which on microscopic examination proved to be an osteogenic sarcoma. However, since the occurrence of this onion-peel formation is quite unusual in any bone disease other than

Fig 2, left. This roentgenogram, a plain film of the abdomen of a patient thought to have acute appendicitis, shows a lesion of the twelfth rib which the roentgenologist believed to be a bone cyst.

Fig 3. The roentgenogram of the same patient whose film is shown in Figure 2. Even after a period of 11 months the roentgenologic findings resemble bone cyst more than Ewing's tumor. The rib was excised and microscopic sections showed Ewing's tumor.

Ewing's tumor, we believe that such a finding is highly suggestive but not pathognomonic of Ewing's tumor.

OPERATIVE FINDINGS AND GROSS PATHOLOGICAL CHANGES

Exploration in some instances revealed a false capsule which was probably periosteum, but in most of the patients there was invasion of the muscle by tumor. Some of the tumors were not very vascular but a few showed extreme vascularity, one of them necessitating the insertion of a gauze pack to control the bleeding which followed excision of tissue for microscopic examination. The color of the neoplastic tissue was gray in the majority of the patients, but in some it was red or purple, because of hemorrhage. Some of the tumors were firm and others were soft and friable.

MICROSCOPIC FINDINGS

There was no stroma between the individual cells, but in most instances there were coarse strands of connective tissue which divided the cells into groups (Figs 5, 9, 15, and 21). Erythrocytes were present in most of the sections. Striated muscle had been invaded by tumor in several instances. Perivascular or perithelial arrangement of cells was noted in the sec-

Fig. 1 The roentgenogram of the scapula shows new bone formation in the so-called "sunray" fashion which is often considered highly suggestive of osteogenic sarcoma. Microscopic section of the tissue removed at exploration showed Ewing's tumor.

Pain The occurrence of pain was recorded in all instances except that of a child with a tumor of the scapula, who was brought to the hospital because his parents noted the presence of a mass.

Swelling Swelling was noted by the patient or his family in all instances except 1 in which the tumor was in the twelfth rib. In 10 patients there had been a slow increase in size, in 4 the increase had been rapid, in 1 patient there had been no change since the mass was first noticed (9 weeks before admission to the hospital), and in 1 patient the presence or absence of this symptom was not recorded. There was a definite history of fluctuation in the size of the tumor in each of 3 individuals. One patient developed a swelling which subsided completely and then recurred and persisted until time of admission to this clinic. In 2 patients the swelling occurred, subsided completely, recurred and subsided, and again recurred and subsided before the third recurrence which failed to regress before treatment.

Fracture A spontaneous fracture occurred in only 1 instance, the patient having fractured the shaft of the femur 15 months after injury and 5 months after the appearance of the tumor.

PHYSICAL AND LABORATORY FINDINGS

Evidence of inflammatory disease There was some evidence of inflammatory disease in all patients. Every individual had an elevation of temperature before operation to 100 degrees F or more. In each of 14 patients there was a rise in temperature before operation to 100 degrees or more, the maximum temperature in any patient having been 103 degrees. In 15 patients there was tenderness over the involved area. In 9 instances it was noted that the skin over the tumor was warmer than elsewhere, in 1 instance there was a statement that the skin was not warmer, and in 1 patient the presence or absence of this sign was not recorded. The minimum leucocyte count was 5,200 and the maximum was 18,000. In 10 patients the white blood cell count was 10,000 or more. The evidence of inflammatory disease was so striking that, before admission, aspiration had been done in 1 instance and incision and drainage in another and, in this clinic, incision and drainage were done in 1 patient.

Characteristics of the tumor In most instances, the tumors were visible and in all patients they were palpable. Most of the tumors were smooth and all of them were firm or hard, and immovable. Although none was fixed to the skin, one (a tumor of the mandible)

Fourteen patients were subjected only to biopsy and irradiation. One tumor was in the tibia and the patient should have been subjected to amputation. It was shown by Lichtenstein and Jaffe (61) that inspection of the gross specimen of a long bone may reveal that the tumor has spread farther than one is led to believe by the roentgenogram. This observation justifies the statement that amputation should be done not through the involved bone but through the bone proximal to it. Thus amputation should be done through the femur for Ewing's tumor of the tibia. In instances of Ewing's tumor of the femur we believe that hip-joint disarticulation should be done, but of our 3 patients with Ewing's tumors in the femora, 2 were subjected only to biopsy and irradiation and the third to high thigh amputation. In cases of Ewing's tumor of the shoulder and pelvic girdle the question of whether to advise radical surgery or irradiation is not definitely settled. Such operative procedures as shoulder girdle amputation and hemipelvectomy are extremely mutilating and are especially undesirable in the young patients affected by this disease. The other two factors which make this subject a controversial one are that cures even by such radical procedures are extremely rare, and that a few patients are cured by roentgen ray therapy alone. We believe that amputation through the humerus or femur and not simple excision of the involved bone should be done for Ewing's tumor of the radius or fibula because of the fact that the greater possibility of cure by amputation outweighs the advantage of the better functional result by simple excision.

Table III shows the sites of involvement, the treatment, and the duration of life after the diagnosis had been made. Of the 14 patients subjected only to biopsy and irradiation, there is only 1 who is still living. Both patients on whom excision of the ribs was done and followed by irradiation are dead. One patient subjected to biopsy, irradiation, and amputation is alive. One of the 2 patients subjected to amputation alone is alive. One patient in whom no treatment was given is dead. Table IV shows the duration of life, after the establishment of the diagnosis, of our 17 patients who died. Five patients sur-

vived less than 6 months and 10 patients survived less than 12 months.

Meyerding (69) from the Mayo Clinic reported that of 114 patients, in 100 of whom the diagnosis had been confirmed by microscopic examination, 21 lived 5 or more years (18.4 per cent). Geschickter and Copeland (35) reported 5 year cures in 6 of 99 patients (6 per cent) who were followed. Coley (13) stated that 3 of 70 patients (4.3 per cent) followed were alive and well 5 or more years after the diagnosis had been established. None of Lichtenstein and Jaffe's (61) 17 patients lived 5 years. Including the 20 patients herein discussed, 3 of whom survived 5 or more years (15 per cent), the total number is 320, with 5 year survivals in 33, or approximately 10 per cent. In a review of the literature on Ewing's tumor it was found impossible to determine accurately the total number of such cases reported and the total number of 5 year cures because some workers reported 5 year survivals without mentioning the total number of tumors they had seen, others reported cases without mentioning 5 year survivals, and still others reported cases which had been reported previously. However, it is thought worth while to report our observations from the literature. The reports were divided into 3 groups: (1) those in which the author gave the total number of cases and the number of 5 year survivals (Table V), (2) those in which 5 year survivals were reported without mention of the total number of cases seen (Table VI), and (3) cases reported without mention of 5 year survivals (Table VII). In group 1 were 386 patients with 48 five year survivals, in group 2 were 3 patients with 3 five year survivals, and in group 3, 176 patients, survivals not mentioned. A summary of the findings in these tables shows that of a total of 565 cases of Ewing's tumor reported in the literature, 51 patients, or 9 per cent, survived 5 years. Nowhere in the literature was a report found in which it was stated that the metastasis from a Ewing's tumor disappeared, without treatment of the metastasis.

CAUSE OF DEATH

Although none of the patients died in the hospital, the reports from the families, family

tions from only 4 patients. Although all of the sections of all of the patients were repeatedly studied only one formation in one section was seen which resembled the rosette seen in neuroblastoma. The nuclei of the cells were round or oval. The chromatin in most cases was finely divided but in a few it was fairly coarse. In 5 instances a single central nucleolus was seen in a type of cell in which the chromatin was fairly coarse. In the majority of sections the cells showed practically no cytoplasm, and in the cells in which cytoplasm was visible it was small in amount and slightly acidophilic in staining reaction. The cell border was indistinct except in one section. There was usually very little variation in the size of the cells. Mitotic figures were few in all except 2 instances, in which they were fairly frequent, being as many as 4 per high power field in one and 3 per high power field in the other. The microscopic patholog-

ic changes were fairly constant and were considered to be typical in 12 of the tumors. In the 8 other tumors, the microscopic findings, although not perfectly typical, were characteristic enough to make the diagnosis of Ewing's tumor incontrovertible.¹

DIAGNOSIS, TREATMENT, AND RESULTS

We believe that it is impossible to make an unequivocal diagnosis of Ewing's tumor by means of the roentgenogram alone and that all such lesions should be subjected to exploration and removal of tissue for microscopic examination. Furthermore, it seems unwise to administer roentgen ray therapy as preoperative therapy or a so called therapeutic test without microscopic confirmation of the diagnosis. Tissue examined after roentgen ray therapy sometimes does not show pathologic changes definite enough to justify the diagnosis of Ewing's tumor and thus the true nature of the disease must always remain open to question. In one case in point (Case 2) the fibula was explored and tissue was removed which showed Ewing's tumor (Fig 9). Inasmuch as the parents of the patient would not permit her to be subjected to an amputation, roentgen ray therapy was given. Later, consent having been obtained, amputation was done, and, although sections were cut from 5 different sites, a definite diagnosis of Ewing's tumor could not be made (Fig 11). In instances of probable Ewing's tumor in a bone such as the ilium, which cannot be removed without extreme mutilation of the patient, tissue for microscopic examination should be removed before roentgen ray treatment is started. In short, the diagnosis of Ewing's tumor should be made by microscopic examination before amputation is done or roentgen ray therapy is administered. In a case of probable Ewing's tumor in a rib, excision of the rib may be done without previous biopsy.

¹Microscopic sections of the tumors herein reported in detail (Cases 1 to 4) were reviewed by E. W. Goodpasture, professor of pathology at Vanderbilt University Medical School and V. C. Foot, professor of surgical pathology at Cornell University Medical College. Dr. Goodpasture agreed with our diagnosis in all instances. Dr. Foot thought that the diagnoses in Cases 1 and 4 were Ewing's tumor. In regard to Case 1, Dr. Foot stated that it could be Ewing's tumor. The invaded muscle looks like it but the bone marrow has the appearance of harboring a growth that is more like angiosarcoma with perithelial proliferation. That type of tumor is one of Ewing's endotheliomas of bone.

Fig 4a

Fig 4b

Fig 6

Fig 5

Fig 7

Fig 4 Case 1 The roentgenogram shows, in the fibula, both "onionpeel" and "sunray" formations, that is, there is new bone formation both parallel and perpendicular to the shaft of the fibula

Fig 5 Case 1 The photomicrograph shows Ewing's tumor cells in the perithelial or perivascular formation

Fig 6 Case 1 The roentgenogram of the stump of the femur made more than 17 years after amputation shows no evidence of neoplastic disease

Fig 7 Case 1 No evidence of metastasis is present in the roentgenogram made more than 17 years after the establishment of diagnosis of Ewing's tumor of fibula

the leg. Aspiration by her family physician obtained blood

At the time of admission to the hospital, the patient's temperature was 99 degrees F and it rose to 100 degrees F the next day. On the lateral and posterior aspects of the leg there was a firm slightly tender, poorly circumscribed mass. Over the tumor the veins were prominent and the skin was warmer than elsewhere. The leucocyte count was 9600.

The roentgenogram (Fig 4) showed a soft tissue tumor of the upper portion of the leg, destruction of the upper end of the shaft of the fibula, and new bone formation both parallel and perpendicular to

the shaft of the bone. The film of the chest showed nothing abnormal.

The clinical and preoperative roentgenologic diagnosis was osteogenic sarcoma.

A tourniquet was placed 1 inch above the femoral condyles and an incision was made over the tumor. After the thinned cortex had been opened, soft tumor tissue was seen, frozen section of which showed malignant tumor. A second tourniquet was placed high on the thigh and a midhigh amputation was done between the tourniquets.

On microscopic examination (Fig 5) the cells were found to be quite uniform with a very small amount

Fig 8a

Fig 10b

Fig 12

Fig 13

Fig 9

Fig 11

Fig 8 Case 2 The roentgenogram shows a small area of bone destruction at a point just distal to the middle of the shaft of the fibula

Fig 9 Case 2 The photomicrograph shows Ewing's tumor

Fig 10 Case 2 The roentgenogram made 40 days after exploration of the fibula and 5 days after the completion of administration of roentgen ray therapy

Fig 11 Case 2 Following administration of 1,000

roentgens through each of two portals to the fibula, amputation was done This photomicrograph of a section of tissue removed from the diseased area shows no cells which can be identified as those of Ewing's tumor

Fig 12 Case 2 The roentgenogram of the stump of the femur made more than 9 years after amputation shows no disease

Fig 13 Case 2 The roentgenogram of the chest, made more than 9 years after amputation, shows no metastases

On microscopic examination the cells were found to be fairly uniform with very little cytoplasm and no distinct cell border (Fig 15) The nuclei were round or oval and basophilic The chromatin was fairly finely divided The tumor had extended into the striated muscle The packing was removed 6 days after operation and roentgen ray therapy was started the next day Over a period of 27 days, 3,200 roentgens were given through each of 3 portals

On February 3, 1941, a roentgenogram of the chest (Fig 16) showed a nodule in the left lung at the level of the second intercostal space and one in the right lung at the level of the third rib These nodules were thought to be metastatic tumor No roentgen ray therapy was administered to the chest Amenorrhea had been present from February, 1941, until August, 1942 A roentgenogram of the chest (Fig 17) made on October 30, 1941, showed that the

of cytoplasm and indistinct cell borders. The nuclei were round or oval and basophilic, and contained chromatin which was fairly finely divided. The perivascular or perithelial formation was quite marked. Although there was very little stroma, a few septa of connective tissue could be seen. The tumor cells had extended into the striated muscle.

Roentgen ray therapy was not given. On April 16, 1948, more than 17 years after operation, her general condition was found to be excellent. The patient was able to walk very well with the help of the artificial extremity. The stump was normal. There were no palpable masses in the stump, inguinal region, or abdomen. Roentgenograms of the stump (Fig 6) and chest (Fig 7) showed no evidence of recurrence or metastasis.

The biopsy was done distal to a tourniquet proximal to which amputation was done. Such a procedure, when possible, seems advisable, to prevent dissemination of the tumor during exploration. However, Case 2 reveals the fact that this procedure is not always necessary to effect a cure.

CASE 2 Surg Path No 10153, Registry of Bone Sarcoma No 2297

The patient was a white girl 16 years of age who was admitted to the Vanderbilt University Hospital on July 1, 1938, complaining of a swelling of the left leg. Four months before admission to the hospital she fell from a truck and injured the lateral part of the left leg. Three days later, swelling, bluish discoloration, and pain occurred. After a few days these signs subsided to some extent, but they again began to increase 2 months later.

On the day of admission to the hospital, her temperature was 99 degrees F. At the junction of the middle and lower thirds of the left leg, there was an annular, firm, slightly tender swelling. The skin over the tumor showed redness and increased warmth. The leucocyte count was 12,000.

Just distal to the middle of the shaft of the left fibula, there was an irregular area of destruction (Fig 8). The roentgenogram of the chest showed nothing abnormal.

Although the roentgenologic diagnosis was osteomyelitis, the clinical diagnosis was malignant tumor, probably Ewing's tumor.

A posterolateral incision was made over the site of maximum swelling. The fibula was rough and surrounded by gray, soft, friable tissue which had extended into the muscle. Several pieces of fibula and tumor were removed and the wound was closed with silk.

On microscopic examination the cells were found to be fairly uniform with very little cytoplasm (Fig 9). The nuclei were round or oval and basophilic. In the majority of the nuclei the chromatin was finely divided but, rarely, a central nucleolus was present. There were a few areas of necrosis. Tumor cells were seen in bone and in striated muscle.

The parents of the child were told that amputation should be done but they refused to give their consent. Seven days after the biopsy the wound disrupted. Twenty-three days after the biopsy roentgen ray therapy was begun and over a period of 14 days a total of 1,000 roentgens was administered to each of 2 portals over the leg (Fig 10) and 1,200 roentgens to the left inguinal region. At this time the parents gave permission for an amputation. Forty-three days after biopsy a supracondylar femoral amputation was done.

On microscopic examination, although sections were made from 5 sites, a definite diagnosis of tumor could not be made (Fig 11). There were a few areas in which cells with round nuclei and little cytoplasm could be seen, but these cells resembled lymphocytes more than cells of Ewing's tumor. There had been considerable replacement of striated muscle by connective tissue.

This patient was delivered of a normal infant July 8, 1947. On February 21, 1948, more than 9 years after amputation, she was in excellent health. She was able to walk very well, using the artificial limb. Examination revealed a well healed incision with a smooth bone end and no inguinal or abdominal masses. A roentgenogram of the stump (Fig 12) showed no recurrence and a roentgenogram of the chest (Fig 13) showed no metastases.

Inasmuch as 43 days elapsed between the biopsy and amputation, what would appear to be adequate opportunity for dissemination of the tumor was present. The roentgen ray therapy was administered because permission for amputation could not be obtained. We see no reason for irradiation preceding amputation.

CASE 3 Surg Path No 13468 Not registered with the Registry of Bone Sarcoma

The patient was a white girl 17 years of age who was admitted to the Vanderbilt University Hospital on December 26, 1940, complaining of pain in the right hip. There had been no injury. Four months before admission to the hospital she began to have pain in the hip and 2 months later she noticed that the right hip was larger than the left one.

The temperature was 99.2 degrees F. In the medial portion of the ilium there was a firm, non-tender, poorly circumscribed mass over which the skin was warmer than elsewhere. The leucocyte count was 7,200.

A roentgenogram showed an area of destruction in the medial portion of the right ilium (Fig 14).

The roentgenologic and clinical diagnosis was Ewing's tumor.

An incision was made over the wing of the ilium and through the muscle. The false capsule of the tumor was incised and there was encountered tumor tissue which was pinkish white, friable, and so irregular that, after several small pieces were removed, packing was required to control the bleeding.

Fig 8a Fig 8b Fig 10a Fig 10b

Fig 11

Fig 8 Case 2 The roentgenogram shows a small area of bone destruction at a point just distal to the middle of the shaft of the fibula

Fig 9 Case 2 The photomicrograph shows Ewing's tumor

Fig 10 Case 2 The roentgenogram made 40 days after exploration of the fibula and 5 days after the completion of administration of roentgen ray therapy

Fig 11 Case 2 Following administration of 1,000

On microscopic examination the cells were found to be fairly uniform with very little cytoplasm and no distinct cell border (Fig 15). The nuclei were round or oval and basophilic. The chromatin was fairly finely divided. The tumor had extended into the striated muscle. The packing was removed 6 days after operation and roentgen ray therapy was started the next day. Over a period of 27 days, 3,200 roentgens were given through each of 3 portals

roentgens through each of two portals to the fibula, amputation was done. This photomicrograph of a section of tissue removed from the diseased area shows no cells which can be identified as those of Ewing's tumor

Fig 12 Case 2 The roentgenogram of the stump of the femur made more than 9 years after amputation shows no disease

Fig 13 Case 2 The roentgenogram of the chest, made more than 9 years after amputation, shows no metastases

On February 3, 1941, a roentgenogram of the chest (Fig 16) showed a nodule in the left lung at the level of the second intercostal space and one in the right lung at the level of the third rib. These nodules were thought to be metastatic tumor. No roentgen ray therapy was administered to the chest. Amenorrhea had been present from February, 1941, until August, 1942. A roentgenogram of the chest (Fig 17) made on October 30, 1941, showed that the

Fig 14 Case 3 The roentgenogram of the pelvis shows an area of bone destruction in the medial portion of the right ilium

Fig 15 Case 3 The photomicrograph shows Ewing's tumor

Fig 16 Case 3 This roentgenogram was made 5 weeks after the ilium had been explored There is a nodule in the left lung at the level of the second intercostal space and one in the right lung at the level of the third rib These nodules were thought to be metastases from the Ewing's tumor of the ilium

Fig 17 Case 3 This roentgenogram was made 8 months after the one shown in Figure 16 The nodules are not visible although this patient received no roentgen ray therapy to the chest

Fig 18 Case 3 The roentgenogram of the pelvis made 7 years after exploration of the ilium shows no evidence of recurrence

Fig 19 Case 3 The roentgenogram of the chest made 7 years after the establishment of the diagnosis of Ewing's tumor shows no recurrence of metastatic nodules

nodules in the lung had completely disappeared There was a considerable amount of calcification in the ilium on this date On September 21, 1944, roentgenograms showed normal lung fields and evidence of bone regeneration in the ilium In April, 1945, the patient was delivered of a 7 months' in-

fant who lived 6 months In October, 1947, she was delivered of a 6 5 months' infant who lived only 2 hours A roentgenogram of the pelvis made on December 4, 1947 (Fig 18), 7 years after operation, showed that there had been no change in the appearance of the ilium since the film was made in

Fig 20

Fig 21

Fig 22

Fig 23

Fig 24

Fig 20 Case 4 The roentgenogram shows areas of decreased and of increased density in the inferior portion of the body of the right ilium and the superior portion of the superior ramus of the pubis

Fig 21 Case 4 The photomicrograph of a section of the tissue removed at exploration of the ilium shows Ewing's tumor

Fig 22 Case 4 The roentgenogram of the chest shows a nodule near the periphery of the upper lobe of the right lung which was thought to be metastatic from the Ewing's

tumor of the ilium and pubis

Fig 23 Case 4 This roentgenogram made 9 months after the one shown in Figure 22 shows that the nodule has disappeared This patient received no roentgen ray therapy to the chest between June 18, 1937 (Fig 22) and March 29, 1938 (Fig 23)

Fig 24 Case 4 The roentgenogram made 3 years after the one shown in Figure 22 shows large masses of metastatic tumor on the right but none at the site of the first apparently metastatic nodule

1944 There was no evidence of metastatic lesions in the chest (Fig 19) On March 3, 1948, she was in excellent health Physical examination showed no evidence of recurrence

The amazing feature in this patient was the disappearance of lesions which roentgenographically appeared to be metastatic nodules Except for the diagnostic chest film, the nodules themselves were not irradiated, although the ilium and, evidently incidentally, the ovaries were irradiated Eight months after their appearance on the film, the nodules disappeared and had not recurred 6 years

later Furthermore, this patient went through 2 pregnancies without reactivation of the disease

CASE 4 Surg Path No 8785 Not registered with Registry of Bone Sarcoma

This patient was a white man, 27 years of age, who was admitted to the Vanderbilt University Hospital on March 30, 1937, complaining of swelling of the bladder One year previously he injured his back and right hip in an automobile accident The pain in these regions subsided after a few days Three months before admission to the hospital he began having pain in the right hip and 1 month later he noticed a tender mass in the right lumbar region

which disappeared after a week. Three weeks before admission a mass appeared in the suprapubic region. This mass steadily increased in size.

The temperature was 98 degrees F and rose subsequently to 100.4 degrees F. In the lower abdomen, extending upward from the pubis, there was a smooth, firm, slightly tender, immovable mass. Rectal examination revealed a mass with similar characteristics. The white blood cell count was 12,400.

A roentgenogram showed that a destructive lesion which involved the medial aspects of the inferior portion of the body of the ilium and the superior portion of the superior ramus of the pubis (Fig. 20).

The clinical diagnosis was tumor of the pelvic bones. The roentgenologist thought that the correct diagnosis was tumor, but stated that the possibility of osteomyelitis could not be ruled out by the roentgenogram alone.

An incision was made near the lateral border of the right rectus muscle and the tumor was exposed retroperitoneally. The tumor tissue was gray, friable, and very vascular. Two pieces of tissue were removed.

On microscopic examination the cells were found to be fairly uniform (Fig. 21). There was a very small amount of faintly eosinophilic cytoplasm, but the cell borders were not distinct. The nuclei were round, basophilic, and contained finely divided chromatin. Small blood vessels were quite numerous.

Six days after operation, roentgen ray therapy was started. Over a period of 17 days a total of 3,200 roentgens was administered through each of 2 portals over the diseased portions of the ilium and pubis.

The abdominal mass decreased in size but did not disappear. On May 20, 1937, a roentgenogram of the chest revealed a large nodule near the periphery of the upper lobe of the right lung. On June 18, 1937, a chest film (Fig. 22) showed that the nodule had increased in size. Although no irradiation was given to the chest except that administered during the 2 diagnostic chest films, the roentgenogram on March 29, 1938, 9 months later (Fig. 23), showed that the nodule had disappeared. On February 4, 1939, no lung metastases were seen on the chest film. On November 1, 1939, a metastatic nodule appeared near the right cardiohepatic angle and on May 29, 1940, several nodules were seen in the right lung, but none in the region where the first metastasis had been seen. Irradiation was administered with some decrease in size of the lesions, but on May 22, 1941, large solid tumor masses were seen (Fig. 24) and roentgen ray therapy was started again. The patient died on October 16, 1941. There never was a recurrence of the nodule that had disappeared without having been directly treated.

The following hypotheses have been considered to explain the disappearances of the pulmonary nodules in Cases 3 and 4.

- 1 They were not metastatic neoplasms.
- 2 They were so radiosensitive that the tiny amount of irradiation from the diagnostic chest roentgenography caused them to disappear.
- 3 Irradiation of the site of the primary tumor activated the cells in the circulation which rendered secondary irradiation to the lungs.
- 4 Irradiation of the gonads changed the hormonal balance in such a way as to establish conditions which were incompatible with life of the tumor cells.
- 5 So called Ewing's tumor is not a neoplastic but an inflammatory disease.

SUMMARY

- 1 The clinical, roentgenologic, operative, and microscopic findings, the treatment, and the results in 20 cases of Ewing's tumor of bone have been described.
- 2 Three instances of apparent cure of Ewing's tumors have been reported.
- 3 Two instances have been recorded in which, without direct treatment, apparent pulmonary metastases from Ewing's tumor disappeared.

CONCLUSIONS

- 1 The bone changes produced by Ewing's tumor of bone and revealed by roentgenography are so variable that a definite diagnosis by that method alone can be made only in the minority of instances.
- 2 No suspected case of Ewing's tumor should be subjected to irradiation or amputation until microscopic examination of excised tissue has confirmed the diagnosis.
- 3 It has been possible apparently to cure this disease in 1 instance by amputation, in another by irradiation, and in a third instance by irradiation and amputation.

THE POSTERIOR SUBSPHINCTERIC SPACE

Its Relation to Posterior Horseshoe Fistula

HAROLD COURTNEY, B S, M D, M Sc (Med), Syracuse, New York

EVEN a cursory review of the literature reveals that the superficial variety of anorectal infections has been covered adequately from every standpoint except the anatomic by many well known authorities. Nearly every writer asserts that an intimate knowledge of the anatomy of these related regions is essential, yet few describe these relationships in detail.

For decades it has been recognized clinically that (1) infection of one ischioanal fossa is often followed by infection of the other, (2) this is especially true in neglected cases, (3) as the infection spreads from one ischioanal fossa to the other, it establishes a "posterior horseshoe fistula" in almost every instance. Yet neither the mechanism of spread nor the reason for its location posterior to the anus has been clear. In view of these facts, I shall explain the anatomic relationship of the anorectum as related to posterior horseshoe fistula. The anatomic relationships revealed by my research are in disagreement with the statements made by many previous investigators.

Some have contended that the so-called "anococcygeal raphe" underlying the anococcygeal skin sulcus, forms a definite barrier to the contiguous spread of infection from one ischioanal fossa to the other. This group is inclined to believe that the infection is transmitted by the lymphatics. Nesselrod has confirmed the belief that the lymphatics of this area are intracutaneous and that they are not deep enough to form the basis of a fistulous tract.

Many proctologists have demonstrated clinically the existence of a communicating tract between the two fossae.

From the Anatomical Laboratories of the Graduate School of Medicine of the University of Pennsylvania under the direction of Oscar A. Batson, M.D., Professor of Anatomy, and the proctologic services at Syron's General Hospital and Olney-Lane County Tuberculosis Sanatorium.

Others have considered the possibility that this tract was represented in normal anatomy by a surgical space. Hirschman was a proponent of this idea and was responsible for its vogue in Philadelphia.

Several terms, such as the posterior triangular space, the postanal space, and the posterior communicating space, have been used by clinicians to designate collections of areolar tissue in this area. Gorsch and Levy have referred particularly to the posterior triangular and communicating spaces and have defined their limits. Their descriptions and schematic figures appear to be based upon clinical deductions rather than upon detailed dissections.

During the study of the muscles and fascia of the pelvis, several undescribed details bearing on this problem came to light. These are the basis of this report.

RESEARCH MATERIAL

Pelves of 8 human cadavers of the negro and white races, male and female, were dissected in detail. Pelves of 40 cadavers of the negro and white races, male and female, were surveyed in the laboratory while dissected by others. This description is based upon a dissection made from both the perineal and pelvic approach and a comparison of the dissection with sagittal, parasagittal, and coronal sections.

TERMINOLOGY

For clarification I shall define and limit the following anatomic terms as used in this paper.

Coccygeal muscular raphe. This is a proposed new term to indicate more accurately the musculo-fibro-tendinous insertions of all three divisions of the inferior layer of the levator (puborectalis, pubococcygeus, and the coccygeus) into the tip and sides of the coccyx, formerly spoken of as the anococcygeal raphe. The term anococcygeal raphe is a misnomer.

Fig 1 Lateral view of dissected male pelvis, showing the distribution of the fibers of the levator and external anal sphincter muscles (Dissection by author) 1, Pubococcygeus, 2, iliococcygeus, 3, coccygeal muscular raphe, attaching to tip and sides of coccyx, 4, posterior subspincteric space, lying between the coccygeal muscular raphe and the coccyx, above, and the posterior insertions of the deep anal sphincter into the skin, along the anococcygeal skin sulcus, below, 5, posterior insertions of the deep anal sphincter into the skin along the anococcygeal skin sulcus, 6, deep external anal sphincter muscle, formed from fibers of the puborectalis, as it winds itself around the bowel

because in no place does this web of muscle fibers attach to, or come in contact with, the anus

Anococcygeal skin sulcus This term indicates the groove, crease, or furrow of the skin normally present in the posterior midline of the body, separating the buttocks. It extends from the anus to a variable point over the posterior surface of the sacrum

Ischioanal fossa This term, used as a synonym for the ischioanal fossa, denotes the boundary more accurately for in no place is this space in relation to the rectum

ANATOMY

The sphincter muscles and the levator muscle fibers were dissected into their components. By doing this, it was shown that a portion of the fibers of the puborectalis (Fig 3, 12), reinforced by fibers of the pubococcygeus (Fig 1, 1) and the iliococcygeus (Fig 1, 2), forms a flat fibromuscular expanse which inserts into the tip and sides of the coccyx. These combined fibers form the coccygeal muscular raphe of our definition (Figs 1, 3, 3, 10, and 4, 11)

Just posterior to the anorectum the remaining portion of the puborectalis winds and en-

Fig 2 Actual close up photograph of the dissection, as shown in Figure 1 (Dissection by author) 1, Pubococcygeus, 2, iliococcygeus, 3, coccygeal muscular raphe, attaching to tip and sides of coccyx 4, posterior subspincteric space, lying between the coccygeal muscular raphe and the coccyx, above, and the posterior insertions of the deep anal sphincter into the skin along the anococcygeal skin sulcus, below 5, posterior insertions of the deep anal sphincter into the skin along the anococcygeal skin sulcus, 6, deep external anal sphincter muscle, formed from fibers of the puborectalis as it winds itself around the bowel

Fig 3 Drawing showing midsagittal section somewhat schematically, illustrating the relationships of the anorectum to the pelvic diaphragm and the anorectal musculature. A window has been cut through the lateral wall of the rectum, layer by layer, to show the relationships lateral to the rectum. (Dissection by author) 1, Combined longitudinal muscle layer (anterior to the rectum). This layer is composed of the longitudinal muscle layer of the rectum, fibers from the levator fascia and fibers from both the superior and inferior layers of the levator. 2, Inferior layer of the puborectalis muscle. 3, Arrow lying in the posterior levator space. This space surrounds the rectum like a horseshoe, with the open end of the horseshoe toward the pubis. 4, Superior layer of the levator muscle. 5, Combined longitudinal muscle layer of the rectum (posterior to the rectum). 6, Fiber from the superior layer of the levator, to the combined longitudinal muscle layer of the rectum. 7, Inferior boundary of the posterior levator space formed behind the rectum by the superior surface of the coccygeal muscular raphe. 8, Iliorectococcygeus muscle formed by fibers from the iliococcygeus (striped), fibers from the longitudinal muscle layer of the rectum (smooth), and a few fibers from the levator fascia. This muscle forms the superior boundary of the posterior levator space behind the rectum. 9, Retrorectal space. 10, coccygeal muscular raphe, attaching to the tip and sides of the coccyx. 11, Posterior subsphincteric space (connecting the two ischioanal fossae) bounded anteriorly, by the posterior surface of the deep external anal sphincter, superiorly, by the inferior surface of the coccygeal muscular raphe, and inferiorly, by the decussating fibers of the deep portion of the external anal sphincter as they insert into the skin. 12, Puborectalis muscle (the sling of the puborectalis behind the rectum). 13, Fibers of the deep external anal sphincter muscle inserting into the skin along the anococcygeal skin sulcus. 14, Deep external anal sphincter muscle (posterior to the rectum). 15, Anal intermuscular septum.

twines itself around the bowel to form the deep external sphincter muscle (Figs 1, 6, 3, 14, and 4, 9). Some of these puborectalis fibers split off and form a flat web which lies inferior to the coccygeal muscular raphe. The fibers of this web, which are the posterior insertions of the deep external sphincter, lie just beneath the skin of the anococcygeal skin sulcus and terminate by inserting into this skin (Figs 1, 5 and 3, 13). Between these super-

ficial and deep muscle extensions, there is a thin mass of fat and loose connective tissue which extends to either side and is there continuous with the fat and areolar tissue of the ischioanal fossae.

This potential fat filled space, for which I propose the descriptive, anatomic name "The posterior subsphincteric space" (Figs 1 and 3, 11) is situated between the muscular wall of the anal canal in front and the coccygeal

Fig. 4 Drawing showing the coronal section of a dissected male pelvis somewhat schematically, illustrating the extent of the posterior levator space posterior to the rectum, and the manner in which the inferior layer of the levator winds itself around the rectum to form the deep external sphincter muscle of the anus. The iliorectococcygeus muscle has been split in the posterior midline and the flaps turned upward. The wall of the posterior half of the rectum has been removed, with the exception of a few muscle bundles of the combined longitudinal muscle layer on each side and a block of the lower end of the internal sphincter muscle on the right. The skin of the anal canal has been removed (Dissection by author). 1, Iliorectococcygeus muscle, 2, superior layer of the levator, 3, inferior layer of the levator, 4, levator muscle (lateral to the point of division into a superior and an inferior layer), 5, muscle bundle from the superior layer of the levator to the combined longitudinal muscle layer of the rectum, 6, muscle bundle from the inferior layer of the levator to the combined longitudinal muscle layer of the rectum, 7, circumanal space, 8, anal intermuscular septum, 9, deep external anal sphincter muscle, 10, puborectalis muscle showing the inferior layer as it winds and entwines itself around the bowel to form the deep external anal sphincter muscle, 11, coccygeal muscular raphe (inferior boundary of the posterior levator space behind the rectum).

hind. On sagittal section the shape of this space varies somewhat, depending upon whether the section is made through the anococcygeal skin sulcus or at points lateral to it. The narrowest part of the space is found by section through the midline of the body (through the anococcygeal skin sulcus) in which plane the space is irregularly elliptical in shape. The actual photographs and drawings give a better idea of the space than the description. In anatomic terms, however, the space may be said to be bounded anteriorly, by the posterior surface of the deep external

anal sphincter (Figs 1, 6 and 3, 14), superiorly, by the inferior surface of the coccygeal muscular raphe (Figs 1, 3 and 3, 10), and, inferiorly, by the decussating fibers of the deep portion of the external anal sphincter as they insert into the skin (Figs 1, 5 and 3, 13). Actually, these several muscle components are derivatives or extensions of the puborectalis muscle.

This posterior subsphincteric space (1, 2, 3, 4) lies in the exact location of posterior horseshoe fistula. It appears then, that this fistula represents the extension of an infection by contiguity

Fig 5 Photograph showing the insertions of the subcutaneous sphincter, the deep sphincter, and fibers from the combined longitudinal muscle layer of the rectum into the skin along the posterior midline. An incision has been made through the skin in the midline (anococcygeal skin sulcus) and extended into the anal canal. The skin edges have been pulled apart and held in place by pins. (Dissection by author.)

SURGERY

Muscles, including their origins and insertions, must be preserved whenever possible if one is to secure the best functional result. In the majority of cases it is unnecessary to make the usual horseshoe-shaped incision, passing around the anus posteriorly, to cure this type of fistula. Curvilinear incisions are made lateral to the external sphincter muscle over the most prominent part of the ischioanal abscess on either side. These incisions are carried anteriorly to the full extent of the abscess cavity and are terminated posteriorly at the lateral margins of the insertion of the anal sphincter into the skin. If a Penrose drain is passed from one incision to the other, through the posterior subsphincteric space, adequate drainage will be secured. The preservation of

the posterior insertion of the anal sphincter into the skin prevents unnecessary loss of sphincter control and the horrible deformity often seen following the use of the horseshoe incision. The lateral incisions must be extensive and the wounds saucerized. However, when the deep spaces are involved (the posterior levator, the retrorectal, and the lateral pelvirectal spaces), it sometimes becomes necessary to make the horseshoe incision in order to follow the deep portion of the fistula tract and to secure proper exposure and drainage of these deeper spaces. In these cases, it is far better to sacrifice the insertion of the anal sphincter into the skin than the insertion of the levator into the tip and sides of the coccyx. Whenever this is necessary, the incision posterior to the anus should be made well up over the coccyx and a flap of skin, including the insertion of the sphincter muscle into it, should be reflected forward until the posterior subsphincteric space is reached.

SUMMARY

Dissection of a series of cadavers has shown a definite, fatty, areolar tract joining the two ischioanal fossae. This tract lies posterior to the anus and between two prolongations of the puborectalis muscle. The location of this space coincides with the location of posterior horseshoe fistula.

CONCLUSION

Since a knowledge of the presence, location, and limitations of every potential space is essential to fistula surgery, and since there has been much confusion as to the exact pathway of posterior horseshoe fistula in the past, it is hoped that this paper will be of some value in clarifying this situation in the future.

THE CRITERIA, CLASSIFICATION, AND TECHNIQUE OF ILIOPECTINEAL (COOPER'S) LIGAMENT HERNIOPLASTY

CLAUD C BURTON, M D , F A C S , Dayton, Ohio

THE acquisition of knowledge of the surgical treatment of hernia entails, among other things, an acceptable yet practicable classification of hernial operations. In a previous publication mention has been made of three major classifications of hernial operations, namely, herniotomy, herniorrhaphy, and hernioplasty. It is not proposed to discuss further herniotomy or herniorrhaphy but we would like to clarify the current conception of hernioplasty. With the universal acceptance of iliopectineal (Cooper's) ligament repairs, hernioplasty has become more inclusive. Currently it connotes a greater scope of plastic variants than it did a decade or so ago when repairs were confined almost exclusively to the use of the inguinal ligament as anchorage for the separated fascial boundary. The recognition of two types of hernioplasty, inguinal ligament hernioplasty, and iliopectineal (Cooper's) ligament hernioplasty, has been helpful and an advance-step in lessening misunderstanding when referring to these plastic reparative procedures. The technical development of the former, with the use successively of fascial sutures, of free or pedicled fascial grafts, of pedicled muscle grafts, and recently of cutis grafts, constitutes one of the most interesting chapters in the progress of hernial surgery. Furthermore, it seems likely that the cumulative story of the progressive evolution of various maneuvers employed in iliopectineal ligament repairs will ultimately be equally as fascinating.

The purpose of this paper is (1) to focus attention on some of the factors which have played a role in retarding the development of the various maneuvers in Cooper's ligament repairs, (2) to present a practical classification and the criteria for each variant, and (3) to describe and illustrate the technique of the combined operation.

In recent years there has been a rising interest in and a general acceptance of iliopectineal ligament hernioplasty, which has been reflected in an increasing number of articles appearing in the literature on this technical aspect of hernia repair. As a result of this transition in technique, the successive variants employed for implementing the coexisting anatomical weaknesses have become standardized and correlated so that the composite operation is rapidly approaching the position of challenging the choice of the inguinal ligament in the repair of certain types of inguinal hernias. In retrospect, it is difficult to understand why anyone familiar with the anatomic relationships in the inguino-femoral region and the dynamics of the progression of the hernia, could overlook for long the inherent advantages of a deeper parietal anchorage and a mechanically better shunting angle to intra-abdominal force which obtain in iliopectineal ligament repairs.

The chief factors which may be considered as playing a contributing role in the reluctance of surgeons to take advantage of this valuable and, for the most part, easily accessible ligament are

1. *The failure of technical progress to keep pace with anatomic knowledge.* Progress in surgery is not wholly dependent on anatomic knowledge, but, sharing importantly in its progress is the ability to recognize discernible technical pitfalls and on the increasingly efficient application of ways of correcting congenital or acquired deficiencies. The latter prerequisite imposes the necessity of constant acquisition of new information. Moreover, we should realize that during the evolution of the modern concept of hernia repair, which had its inception only a half-century ago, the opportunities for surgical training in herniology were far less than in the present day of industrialization in which operative repair of hernia is universally accepted as the treatment of

choice In the former era of surgery, hernias were not operated on unless they became strangulated or reached a size incompatible with gaining a livelihood, while in the present era many hernias are repaired that were previously unrecognized by the individual and were only discovered during a pre-employment examination or on induction into military service Consequently, the opportunity for surgical experience in the treatment of hernia in its incipency, as contrasted with the prevalent scrotal hernia of a half-century ago, has increased manifoldly Moreover, during this interim there has been a decided trend toward internal or deeper repair by the correction of the saccular weakness intraperitoneally and the use of Cooper's ligament as anchorage for the wall, in contrast to the former practice of extraperitoneal removal of the sac, reinforcement of the anterior layers of the wall and the employment of the inguinal ligament as the sheet anchor

2 *The erroneous but prevailing concept of the origin and eradication of the femoral variant of the sac* Because of earlier reports of the low incidence of recurrence of femoral hernias repaired by the inferior or femoral approach, a technique which precludes total removal of the sac, surgeons generally gained the erroneous idea of the efficacy of this technique It did not occur to them to challenge the technique on anatomical grounds or to analyze and re-evaluate the source of the statistical data which were obtained from small series of patients operated upon and from what is currently recognized as incomplete follow-up records It is therefore not surprising that there has been professional resistance to any suggestions for alteration of the conventional technique of saccular ligation from below, usually implemented by the suturing of the inferior margin of the inguinal ligament to the pectineal fascia or occasionally to Cooper's ligament, a technique which had been in effect for a quarter of a century Statistical surveys of the last decade have shown that the inguinal approach is favored over the femoral and coincidentally with decreasing incidence of inguinal and femoral recurrences McClure and Gallis (1939) in their series of 90 femoral hernias found that 22.3 per cent had been op-

erated on previously for inguinal hernia on the same side These findings suggest that the patients were subjected to two operations because of a diagnostic error or that more than casual relationship exists between femoral and inguinal hernias

The superiority of the inguinal route lies in providing (1) greater accessibility to the sac and its variants, (2) better definitive exposure of the wall adjacent and remote to the defects in the floor of the canal as well as those occurring in the interligamentous space, (3) more accurate evaluation of the composite weaknesses and of the neighboring structural integrity, and (4) complete visualization of the iliopectineal ligament and triangular space Consequently, the superior approach has increased the anatomical frontiers of the congenital and distortion weaknesses of the inguina and coincidentally has extended the surgical horizon of hernia repair This composite concept of inguinofemoral herniation provides the resourceful surgeon with a wider range of ingenious maneuvers for augmenting the combined inguinopectineal or three dimensional repair Simultaneously with the almost universal acceptance of the principle of retrogressive mobilization and conversion of the various locules into the parent sac before total exsection, there has come a revival of the concept of triangulation of the inguina which was originally proposed by Hesselbach in 1806 Ferguson, and Andrews and Bissell recognized the importance of the smaller internal inguinal triangle in the development of incipient direct hernia, and emphasized the necessity for reinforcing the wall overlying the internal fossa in the prevention of recurrences of this type of hernia

Ordinarily we are prone to think only of the urogenital and vascular orifices in or adjacent to the floor of the canal as sources of the hernia, overlooking the other rare but equally important congenitally susceptible mural or ligamentous weaknesses Yet, in Cooper's book published in 1804, there is a plate depicting 6 such orifices Anatomically and surgically there is currently recognized 12 or more actual or potential areas of weakness through which herniations have occurred It would therefore seem logical for the purpose of exactness of

their location to describe them in relation to the triangles of the inguina. Burton and Dugdale have revived and extended this idea by considering the entire hernia-bearing region as a composite unit or the inguina. Each inguen is triangularized by dividing it into (1) a major superior triangle, which lies anteromedial to the inguinal ligament and comprises Hesselbach's and a medial triangle, and (2) a major inferior triangle which is inferomedial to the inguinal ligament or trihedral space. It consists of the lesser vascular and the muscular triangles, respectively. Therefore, by correlating the saccular and triangular relationship one can better understand the validity of the retrogressive removal of the saccular variants and better define adjacent structural elements preparatory to the creation of barriers to prevent recurrence of the herniation.

Unfortunately, in descriptions of inguinal and femoral hernias, so complete has been the regional bias that each area has usually been discussed with little regard to the anatomical relationships or the continuities of the fascial layers therein.

3. *Failure explicitly to set forth criteria for iliopectineal (Cooper's) ligament hernioplasty.* Experience gained from contact with the resident staff has revealed that they seldom have any preconceived idea as to what structural deficiencies or parietal distortions warrant the use of the iliopectineal ligament in hernia repair. There is a common tendency, which is a valid one, to employ it in all refractory hernias, included in this category are most preternaturally large recurrent hernias. They are confounded as to what saccular variants or precise structural deprivations constitute the indications for a Cooper's ligament repair. This lack of complete understanding of the relationship of the various anatomical weaknesses is due in part to the paucity of the literature on this etiologic aspect of hernia but is many times traceable to the delinquency of the senior surgeons who have inadvertently failed to point out the reasons for the application of this progressive step of employing the iliopectineal ligament in the radical treatment of hernia.

The criteria for the employment of Cooper's ligament may be classified as absolute and

equivocal. The absolute are (a) all femoral loculations of the sac and (b) inadequacy of the inguinal ligament. The equivocal indications are (a) multiple coexisting saccular locules, (b) generalized parietal laxity of the inguina, (c) fascial incompetency, which not infrequently is associated with aponeurotic or interfascicular defects, (d) refractory hernias or the presence of any marked distortional anatomical pattern as obtains in plural recurrences, (e) certain extrinsic factors such as the constitutional habitus and particularly those individuals suffering from asthmatic bronchitis or chronic recurring coughing paroxysms. It is realized that some of the correlative indications enumerated in the equivocal group fall within that controversial frontier which is only measurable by surgical experience.

CLASSIFICATION OF ILIOPECTINEAL LIGAMENT HERNIOPLASTY

The hernia-bearing region of either lower abdominal quadrant is commonly referred to as the inguinal region and less frequently as the groin. This large triangular area is bounded by the inguinal ligament, the rectus sheath, and the ilioumbilical line with the pubic spine as its apex (3). Such an anatomical concept envisages herniations through the floor and cranial portion of the canal as well as spontaneous hernias in the semilunar and semicircular lines (spigelian). The other triangular component which is more deeply placed lies inferior and medial to the inguinal ligament with Cooper's ligament as its deeper boundary and the spinoeminental line, its superior limit, is known as the inferior inguinal region, interligamentous or trihedral space. Similarly, the composite superior and inferior inguinal regions are designated the inguina. By the foregoing triangulation of the inguina there is more accurate orientation and correlation of the various saccular and structural departures.

Surgeons have long searched for a single anatomic approach through which all protean weaknesses of the inguina can be corrected. Such a route should fulfill the following prerequisites: (1) afford adequate exposure to meet any contingency that has developed in

Fig 1 The anatomy of the inguen is illustrated depicting the important anatomical structures which are encountered in performing the combined inguinopectineal repair. Attention is called to the relationship of the inguinal and iliopectineal relationship of the inguinal and iliopectineal (Cooper's) ligaments. The epigastric vessels which lie in the superior triangular space are constant and are routinely ligated. The obturator vessels are frequently anomalous but their most frequent relationship is shown, which is in the inferior triangular space. They cross the superior pubic ramus juxtamedial to the external iliac vein and when in this position are routinely ligated. The ligation of these vessels exposes the iliopectineal ligament to the level of the external iliac vein, so that wide anchorage of the parietal wall to this ligament is possible.

the progress of the hernia or which may arise during the course of the operation, (2) possess flexibility in dealing with definitive and congenitally susceptible weaknesses, (3) facilitate saccular exsection inclusive of aberrant locules, and (4) permit leeway for the exercise of ingenuity of the surgeon in the creation of a deeply placed unyielding floor. It is our contention that the inguinal approach of Lotheissen meets all the requirements as outlined for the employment of the iliopectineal ligament in hernia repair. However, because of the frequency of diverse and occasional anatomic or embryonic inguinofemoral weaknesses which may coexist, this foundational approach to all inguinal triangles makes possible many intrinsic maneuvers for augmenting definitive mural, intraligamentous or interligamentous defects. These technical variants have been classified according to their evolutionary de-

velopment into (1) femoral hernioplasty, (2) pectineal hernioplasty, (3) inguinopectineal hernioplasty, and (4) combined inguinopectineal hernioplasty.

1 *Femoral hernioplasty* This technical procedure was the first evolutionary step in the departure from the conventionally used inguinal ligament. It constitutes the simplest type of Cooper's ligament repair. The technique was originally proposed by Sir Astley Cooper but it was Annandale in 1876 who made practical application of it. Rugg in 1892 advocated its employment routinely in all femoral hernias. The operation entails ligation of the femoral locule, followed by either occluding the femoral ring with a plug of redundant tissue or by its direct closure by suturing the anterior margin of the ring to Cooper's ligament. The normal relationship of the cord or parietal structures are not disturbed. Like other maneuvers there are certain limitations imposed on this procedure. The hernia must be exclusively femoral, and there must be no coexisting mural weakness. Unfortunately, these criteria seldom exist alone. The operation is the counterpart of the early inguinal herniotomy of Ferguson in which the indirect locule is ligated but the floor of the canal is not mended and the position of the cord is not altered.

It should be an unvarying rule in every hernia operation to expose the peritoneum at the internal ring first. From this pivotal point, all saccular variants are successively mobilized. The presence of a femoral loculation is an absolute indication for iliopectineal repair. It differs from the indirect locule in its location and the fact it does not arise from a vestigial remnant. Its site of exit is through the velamentous fascia in the interligamentous space and usually through an enlarged femoral ring. By tracing intraperitoneally the origin of the different variants of the sac, it has been observed that the femoral outpouching arises from the inferior convex portion of the direct component of the sac. Ordinarily with the intraperitoneal approach the femoral protrusion and its fatty envelope can be easily withdrawn through the femoral ring. If the hernia is incarcerated it may be necessary to suture the lateral margin of the lacunar ligament.

which will facilitate intrapelvic delivery of the incarcerated mass. After the femoral locule is inguinalized the direct component of the sac is freed and indirectized. This retrogressive procedure of mobilizing the sac intraperitoneally and intrapelvically is of imminent importance but unfortunately this technique of total saccular extirpation is not universally followed.

The infraligamentous approach to a femoral hernia has many disadvantages: (1) it provides accessibility only to the femoral variant of the sac, (2) it is not possible through this route digitally to examine the sac for other communicating locules which frequently coexist, (3) there is greater likelihood of injuring incarcerated bowel or if it should be suddenly released the surgeon may not be able to ascertain its viability before it disappears into the general peritoneal cavity, (4) a total excision of the femoral locule is more difficult, (5) should a loop of incarcerated bowel become gangrenous, its resection and anastomosis of the viable ends as advocated by Dennis and Varco could not be done through the inferior exposure.

The second maneuver in femoral hernioplasty is the closure of the ring. This is done by bringing the anterior margin of the ring, which is the inferior edge of the inguinal ligament, down to the iliopectineal (Cooper's) ligament by means of either a silk or a living fascial suture. If the femoral ring is dilated and the inguinal ligament unyielding, precluding its apposition to Cooper's ligament without tension, a fascial suture is preferable. Carscadden and Payne adapted the principle of McArthur by using a strip of external aponeurosis as a suture to bridge the annular defect. A Gallie free fascia lata suture serves equally as well. Dowden contends that the walls of the femoral ring are too rigid to be amenable to sound and reliable approximation. He therefore proposed buttressing the ring by suturing the bunched-up stump of the sac, properitoneal fat or omentum, so as to overlie and occlude the entrance to the canal. The prototype of this technique was employed to occlude the internal abdominal ring by Macewen in 1886 and McLewen in 1890 but was subsequently abandoned.

Fig. 2 The first fascia lata suture is started, showing it autotransfixed after passing through the edge of the medial aponeurotic flap and the fascia transversalis and through the iliopectineal ligament near the inguopectineal junction, posterior to the pubic spine.

Because of its limitations, femoral hernioplasty without implementing it with some other maneuver is rarely employed.

2 Pectineal hernioplasty This operation consists of two steps. The first entails the removal of the sac inclusive of all its locules, the second entails the exclusion of the femoral ring and the repair of the wall by suturing the fascia transversalis alone, or jointly with the other parietal strata, to the iliopectineal (Cooper's) ligament, starting deep to the pubic spine and continuing to the medial border of the external iliac vein.

In the presence of a coexisting saccular and mural hernia, additive reparative measures are called for. The sac is first disposed of in the conventional way. When the parietal insufficiency of the floor of the canal is chiefly of the atonic type, a special effort is directed toward taking up the slack by the creation of a deeply placed wall, which is also strategically more secure. By the utilization of Cooper's ligament as anchorage, the angle of diversion of the wall with the pelvis becomes more acute, thus lessening the concavity of the inguinal fossae; coincidentally there is early shunting of the intra-abdominal thrust. Figures 2 and 3 depict the attachment of the fascia transversalis and medial aponeurotic flap jointly to the iliopectineal ligament with a living fascial suture. The suture begins posterior to the pubic spine and progresses lateralward to the medial border of the femoral vein. This point is usually marked by a minute bony ridge paralleling the vessel or less

Fig 3 The first fascial suture has progressed from the caudal end of the iliopectineal ligament to the external iliac vein where it alters its direction, leaving the iliopectineal ligament and becoming more superficial. From this transitional point it passes through the parietal wall (internal and external oblique) and through the inguinal ligament successively to the newly placed external ring which now lies cephalad to the internal abdominal ring. The cord is displaced with concomitant reversal of the obliquity of its transparietal portion. A relief incision medially placed in the anterior rectus sheath is occasionally necessary to release undue tension on the fascial suture. The insert shows in greater detail the placement of the suture at the transitional space.

frequently by a small eminence on the superior pubic ramus. At this juncture, the suture changes its direction and passes from the iliopectineal ligament through the inferior margin of the inguinal ligament. It continues successively through the internal-external oblique strata and the inguinal ligament to the external ring. In this technique the external ring is reversed and occupies a position cephalad to the internal abdominal ring. The cord is transposed extra-aponeurotically. It should be noted that in the placement of this suture the wall is moved medial and deep to the femoral ring and interligamentous space.

A prerequisite to a pectineal hernioplasty is an available, competent fascial stratum. In the event the fascia transversalis becomes stretched, the medial denser portion near its conjunction with the rectus sheath may be brought down to the ligament. Should this maneuver cause undue tension of the fascia, a vertical or curved incision through the anterior rectus sheath, as suggested by Fallis and Tanner, respectively, will permit sufficient fascial separation without predisposing to any underlying weakness to relieve the abnormal tautness of the fascia transversalis. In our experience the Gallie fascial suture is

ideally suited for this step of the repair. The suture is easily obtainable, strong, somewhat elastic, nonirritating, lasts many years, produces broader contacting surfaces and its placement is accompanied by minimal trauma.

3 *Inguinopectineal hernioplasty (closure of the interligamentous space)* The interligamentous, inguinopectineal or trihedral space lies between the inguinal and iliopectineal ligaments and the anterior abdominal wall. Its superior limit is the internal ring and it extends inferiorly to the pubic spine. As a potential source of weakness this space has received only passing attention. In the conventional or classic hernia operation this vulnerable area is usually given little consideration. In modern textbooks of surgery no mention is made of the importance of reinforcing the velamentous fascia of this space or of stabilizing the inferior edge of the inguinal ligament. Statistically there are no reports incriminating this area as a possible cause of recurrent herniations other than femoral ring, yet, not infrequently one encounters a diffuse bulging through this subinguinal space. This singular lack of recognition or its proper evaluation in hernia repair is explained on the ground there is no classification for

herniation through the interligamentous space unless it is considered a variant of femoral hernia. The only exception is Wilmoth's classification of femoral hernia into prevascular, pectineal, translacunar, and multidiverticular. Too often, we are prone to think of femoral hernia as coming through only the femoral ring rather than bulging through the inguinopectineal space.

The idea of closing the interligamentous space is not new. Fabricius (19) divided the inguinal ligament to facilitate its approximation to the pubic ramus. Subsequently this principle was revived by Litsitsyn and Cheever who modified it by staggering the sectioning of the ligament. While there is concurrence in the objective to be attained by this maneuver, nevertheless the repair of such a strategically important structure as the divided inguinal ligament is an objectional feature which is almost as serious as the correction of the initial weakness. This perhaps accounts for the paucity of surgeons using this departure in technique. Moschowitz in 1907 popularized the earlier novel idea of Ruggi of obliterating the interligamentous space by suturing the recurved portion of the intact inguinal ligament to the iliopectineal (Cooper's) ligament but omitted the previous objection of cutting the former. Since Cooper's ligament is a constant fixed structure of unvarying density, success of the Moschowitz operation is dependent upon the pliability of the inguinal ligament, permitting it to span this vulnerable space. The pitfall of this technique is the tendency forcibly to displace a tense inguinal ligament in an endeavor to close the interligamentous space, unmindful of the fact that the maneuver is unphysiological and frequently results either in tearing the ligament or in cutting through of the silk sutures. Too often the ultimate outcome is the return of the sutured structures to their former position. To obviate this objectional feature an autogenous fascial suture may be interlaced between the ligaments, in effect to form a permanent fascial barrier (Fig 5a).

Another simple but effective method of reinforcing the interligamentous space is the reflection of the lateral aponeurotic flap medially and inferiorly. Ordinarily the flap is

Fig 4 The first fascial suture has been laid. It may or may not encircle the cord at the external ring, depending upon its length and the preference of the surgeon. The space between the inferior edge of the inguinal ligament and Cooper's ligament (interligamentous space) has not been obliterated. By attaching the parietal wall well laterally so that it is contiguous with the external iliac vein, the femoral ring is excluded and lies superficial to the first imposed parietopectineal barrier.

of sufficient width to allow its edge to be sutured to the iliopectineal ligament without tension (Fig 5b). The converging medial and lateral aponeurotic flaps which are anchored to the iliopectineal ligament producing a narrow gutter superjacent to the ligament. By suturing the adjacent surfaces of the aponeurotic flaps, the depression will be smoothed out and the wall further strengthened. This method of obliterating the interligamentous space is technically easier, more physiological and since there is fascia-to-fascia contact it lessens the need for a living suture.

In placing the inguinopectineal hernioplasty in its proper perspective in relation to allied maneuvers, it would seem rational to use it as an adjunctive rather than a basic maneuver.

4 *Combined inguinopectineal hernioplasty (The composite operation or three dimensional repair)* The preceding variants in technique have been successful when measured in terms of comparative results and invaluable in contributing to the progressive security of the wall. But, each maneuver was designed to correct a specific anatomical deficiency and consequently they each have their limitations. It is not uncommon for the surgeon to be confronted with plural and varied weaknesses coexisting in the superior and inferior inguinal triangles, the correction of which no single technical maneuver would suffice. An analysis of the criteria for the various maneuvers has led to the conclusion of proposing a composite

Fig 5 a, left, The second step of combined operation has for its objective the closing or reinforcement of the interligamentous space. It begins with the placement of second fascial suture which passes through the loops of the first fascial suture and through the inferior edge of the inguinal ligament running from the pubic spine laterally to the transitional angle. The suture serves as a living fascial barrier, in the event the inguinal ligament is taut and cannot be apposed to the iliopectineal ligament. b, The second fascial suture starts at the pubic spine but anterior to the first, going through the first loop of the first fascial suture and through the turned down edge of the lateral aponeurotic flap.

operation compounding the advantages of the several standardized technical variants employed in the evolution of Cooper's ligament repair.

TECHNIQUE OF COMBINED OPERATION

Certain cardinal principles, such as mobilization and excision of all locules of the sac and defining the anatomical structures of the floor of the canal are commonly agreed upon by all surgeons preparatory to proceeding with the repair. Therefore, these preliminary features of the operation will be omitted from the description. An inguinal approach is used. The first step of the composite operation is identical with pectineal hernioplasty. As suture material we prefer two fascia lata strips as described by Gallie and LeMesurier. Strategically, this is considered the most important maneuver of the operation for, if this defense barrier fails to hold, the subsequent adjunctive maneuvers are jeopardized. Attention is drawn to certain minor technical departures which will shorten the operating time without compromising the integrity of the wall. In our earlier experience only the fascia transversalis was apposed to the iliopectineal ligament. It was recalled that Joyce sutured the fascia transversalis and medial aponeurotic flap jointly as one stratum to the recurved portion of the inguinal ligament. He reported an enviable recurrence rate using this tech-

nique. We simply adapted the principle of Joyce but substituted the iliopectineal ligament for the inguinal ligament.

The first fascial suture passes through the fascia transversalis and medial aponeurotic flap and then through Cooper's ligament respectively (Fig 2), which is continued in the manner to the external iliac vein. The vein is displaced and protected with the finger or placement of the last suture in Cooper's ligament (Fig 3). At this point the fascial suture changes its direction, which is at the level of the iliac vein where it crosses Cooper's ligament and runs obliquely cephalad, passing through the inguinal ligament and pectineal strata to the newly created external ring. In effect, this closure reverses the obliquity of the transparietal portion of the canal. The transition from the iliopectineal ligament to the inguinal ligament is of crucial importance for it is the most frequent site of recurrence in this type of repair. It is therefore essential that great care be exercised in the placement of the transitional suture as it passes through the adjacent strategic structures, the parietal wall, iliopectineal and inguinal ligament respectively (Fig 3). Since this is a transitional space a continuous or figure of eight suture superior to interrupted sutures. Moreover, because of easy compressibility of the external iliac vein which conceivably could occur from intra-abdominal pressure it is

Fig 6 a, left, The second fascial suture is reversed and imbrication of the lateral aponeurotic flap begun. It passes through the edge of this flap and through the ventral surface of the medial b, The second fascial suture continues cephalad passing through the same structures, which pulls the lateral aponeurotic flap down to the iliopectineal (Cooper's) ligament. This maneuver obliterates the interligamentous space from the pubic spine to the medial border of the external iliac vein where the suture is reversed.

Fig 7 a, left, Completion of second fascial suture. In this three dimensional repair there is reinforcement of the floor which is more deeply placed, implemented by closure of the interligamentous space. The cord is transposed extraaponeurotically and the transpanetel portion points cephalad b, The second fascial suture has been reversed and runs caudally through the ventral surfaces of the inverted medial and lateral aponeurotic flaps, which eliminates the gutter suprajacent to the superior pubic ramus and completes the all fascial closure. The cord is placed extraaponeurotically.

ous that the potential vulnerability of this space cannot be totally eliminated.

In the placement of the first fascial suture, which is the first step of the combined operation, it is essential to have adequate exposure of Cooper's ligament. Routinely ligating the epigastric vessels and also the obturator vessels when present will be helpful. An ingenious maneuver has been described by Rees in which the direction of the femoral vein is changed from 15 degrees inward to 35 degrees outward by abduction of the hip. It would facilitate the placement of the lateralmost and deepest sutures in the iliopectineal ligament.

In those cases in which the fascia transversalis is attenuated, producing in effect a fascial

gap in the floor, there have been proposed three methods of augmenting it (1) By making a relief incision in the rectus sheath (Fig 3), the components of the aponeurotic stratum may be displaced lateralward and overlie the subfunicular area of weakness, or the fascial sheath may be reflected and sutured to Cooper's ligament. The objection to the latter is that it predisposes to herniation by the creation of a spindle-shaped gap at the lateral border of the rectus muscle. (2) Another method is by weaving a living fascial suture between the medial fascial boundary and the iliopectineal ligament. In this way a permanent fascial barrier is formed spanning the vulnerable floor. (3) Perhaps the method that

is rapidly gaining favor is a combination of the relief incision of Fallis with a fascial suture

The primary objectives of the second step of the combined operation are obliteration of the interligamentous space and the stabilization, rarely the replacement, of the inguinal ligament. For the most part, it concerns the details in the placement of the second fascial suture in the alternate maneuvers depending on whether the interligamentous space is closed by a living suture or by turning down the lateral aponeurotic flap. Figures 5a and 6a show the second fascial suture passing through the loops of the first and through the inferior edge of the inguinal ligament beginning behind the pubic spine and continuing to the external iliac veins where it is reversed and returns attaching the edge of the lateral flap to the anterior surface of the medial. Figure 5b depicts the alternative technique in which the second suture passes through the loops of the first and through the turned down edge of the lateral flap. It continues in this manner to the external iliac vein or transitional level where it is reversed (Fig 6b and 7b) passing through the adjacent anterior surfaces of the aponeurotic flaps. In both variants the cord is transposed extra-aponeurotically.

In those rare instances in which the inguinal ligament is totally absent, usually having been destroyed by trauma or infection following a previous repair, Wilmoth has constructed an inguinal ligament by raising a pedicled rectangular flap of the tensor fascia femoris muscle with its enveloping fasciae. The flap is swung into the inguen below the anterior-superior spine of the ilium. Its inferior edge is sutured to Cooper's ligament from the pubic spine to the iliofemoral vein. This unique variant of Wilmoth is worth remembering, but it has not been used in our experience.

CONCLUSIONS

1 Iliopectineal (Cooper's) ligament hernioplasty has been defined in the light of present progress, distinguishing it from the conventional inguinal ligament hernioplasty.

2 Factors responsible for the reluctance of surgeons to accept Cooper's ligament repairs have been discussed.

3 Absolute and equivocal criteria for the combined operation are given.

4 A classification of iliopectineal ligament hernioplasty has been presented from the point of view of evolution and correlation of the various technical maneuvers with the vulnerable area for which each variant was designed to correct.

5 A composite operation incorporating the different reparative departures of Cooper's ligament technique is submitted.

6 Often, because of one's enthusiasm there is a tendency to prejudge a technique before there is available adequate follow-up statistics. This should restrain our expectancy for any new or revived maneuver, no matter how valid it may seem at first. Fundamental principles, anatomical and surgical, still hold. The correlation of the weakness present with the knowledge of the available means for its repair remains paramount in the treatment of hernia.

SUPERFICIAL LOBECTOMY AND TOTAL PAROTIDECTOMY WITH PRESERVATION OF THE FACIAL NERVE IN THE TREATMENT OF PAROTID TUMORS

D STATE, M D , F A C S , Minneapolis, Minnesota

ALTHOUGH mixed tumors of the parotid gland are relatively infrequent (comprising about 4 per cent of all tumors of the oral cavity and adjacent region) (12) still the high incidence of recurrence following excision gives them added importance. The recurrence rates of between 20 to 40 per cent (5), are due mainly to inadequate excision of the neoplasm. The very fact that the tumor is usually poorly encapsulated and contains myxomatous tissue, is probably directly responsible for its incomplete removal when the surgeon attempts to enucleate the tumor from the surrounding parotid tissue. Inadequate excision is also encouraged by the fear of injury to the facial nerve. By the usual surgical approach, the facial nerve is not visualized and consequently its position in relation to the tumor is unknown. The results of injury to the seventh cranial nerve are so blatantly evident that one can readily appreciate the tendency for the surgeon to be most conservative in an effort to avoid this disaster.

Recurrences following surgery are of importance because they tend to grow rapidly and disseminate far into normal tissue. Further, about 25 per cent of mixed tumors (14) tend to become malignant following the appearance of recurrent growths.

ANATOMICAL CONSIDERATIONS

Anatomy textbooks (10) usually describe the seventh cranial nerve as running through the parotid gland. The careful dissections of McWhorter, however, showed that the facial nerve does not run through the parotid gland but rather it courses between the superficial and deep parts of this salivary gland. Our dissections on the cadaver substantiate McWhorter's findings.

The nerve has the same relationship to the two parts of parotid gland as a bookmarker has

to two pages of a book that it separates. After emerging from the stylomastoid foramen the nerve passes anteriorly and laterally to the mastoid process and then comes to be deep to the superficial portion of the gland. The nerve is then split into two main divisions, the temporofacial and cervicofacial nerves by the isthmus connecting the deep and superficial portions of the parotid. These divisions in turn, divide and emerge at the anterior border of the parotid as five terminal branches (Fig 1) the temporal, zygomatic, buccal, mandibular and cervical nerves.

McCormack, Cauldwell, and Anson have described in detail the variations of the terminal divisions of the seventh cranial nerve and the anastomosis connecting the cervicofacial and temporofacial divisions. Furthermore, they have confirmed the findings of McWhorter concerning the relationship of the facial nerve to the superficial and deep part of the gland.

The parotid has no true capsule. It is covered laterally by the parotidomasseteric fascia which is tough and dense posteriorly but becomes thin and fades at the anterior border of the gland. The gland lobules are held together by thin areolar tissue and this same type of connective tissue separates the medial surface of the superficial part of the gland from the facial nerve. The isthmus forming the superficial and deep portion of the parotid varies considerably in thickness, in fact, it may be entirely absent. The deep portion of the gland is wrapped about the external carotid artery and its two terminal branches, the internal maxillary and superficial temporal arteries. The posterior facial vein which is formed by the union of the superficial temporal and middle temporal veins passes down in the substance of the deep lobe of the parotid with the external carotid artery.

Fig 1 Skin flap dissected to expose entire superficial lobe of parotid. Dissection in the plane between the facial nerve and gland is begun anteriorly. The injection of a few cubic centimeters of saline in the loose areolar tissue between the parotid and the nerve aids the dissection. Insert shows skin incision.

OPERATIVE TECHNIQUE

The anesthesia used is Baird's solution (pentothal-curare solution) with oxygen administered through the intratracheal tube (4). The incision (Fig 1) extends vertically from the zygomatic process to a finger-breadth below the angle of the mandible and then forward to the posterior border of the submandibular gland. The vertical component of the incision passes through the natural longitudinal skin creases immediately in front of the external ear and hence is barely visible after it has healed. The horizontal component is similarly well hidden under the ramus of the mandible. The skin flap is then raised and dissected anteriorly until the anterior border of the parotid and the parotid duct are visible beneath the thin, fading parotidomasseteric fascia. This initial dissection of the skin flap must be done with meticulous hemostasis for the planes of dissection which must be obtained can readily be missed in a field which is being covered with blood from multiple small oozing points.

Beyond the medial (deep) to the exposed superficial portion of the parotid the terminal

branches of the facial nerve are readily seen (Fig 1). The parotid duct is next identified and transected. The distal end is tied with a No. 0000 suture and the proximal end is similarly treated, with forceps left attached so that gentle traction may be placed upon it. With any of the readily visible anterior terminal branches of the facial nerve as a landmark, blunt dissection is carried out gently and carefully by spreading with small curved mosquito forceps. The plane that must be entered is that between the medial (deep) surface of the superficial part of the parotid and the branches of the facial nerve. This plane is composed of loose areolar tissue and to facilitate its recognition gentle traction outward is put on the transected proximal end of the parotid duct. A few cubic centimeters of saline solution containing 6 drops of adrenalin to the ounce are also injected into this plane, so that an artificial separation is produced between the gland and nerve. The adrenalin causes local vasoconstriction and aids in effecting hemostasis. The dissection proceeds from the anterior border of the gland posteriorly until the level of the isthmus is reached (Fig 2). Greatest difficulty is experienced in starting the dissection anteriorly and particularly about the parotid duct where almost invariably several small communicating nerve fibers are closely adherent to the lateral aspect of Stenson's duct. The fact that this dissection must be done carefully, gently, and without haste cannot be too strongly emphasized. When the isthmus is reached the site of bifurcation of the main trunk of the facial nerve can be readily visualized and thus avoided in the remainder of the dissection. The posterior border of the superficial portion of the parotid is next dissected from the external auditory canal and adjacent sternomastoid muscle. This portion of the dissection is vascular and must be carried out slowly and carefully. By carrying this dissection anteriorly the isthmus and the seventh cranial nerve is again reached. By transecting the isthmus the superficial portion of the gland is removed. The deep portion is removed (Fig 3) by transecting the external carotid artery and posterior facial vein at the inferior border of the deep lobe, the superficial temporal artery and vein at the superior border and the inter-

Fig 2 Superficial lobe of parotid dissected back to isthmus already transected. Note relationship between facial nerve and superficial and deep portions of parotid.

Fig 3 Superficial portion of gland has been resected. The facial nerve is retracted and the deep portion of the parotid is removed.

nal maxillary artery at the mid-portion of the anterior border of the deep lobe. By elevating the facial nerve with a nerve hook the deep part may be dissected away from the main stem of the nerve and lifted out as a separate unit.

The operative site is checked carefully for bleeding points and after thorough irrigation with saline solution, the subcutaneous tissues of the incision are approximated with No. 000 plain catgut and the skin is closed with interrupted No. 0000 silk. A small Penrose drain is brought out through a small stab wound posterior to the incision in a dependent portion beneath the angle of the mandible. This is left for 48 hours only.

INDICATIONS FOR SUBTOTAL AND PARTIAL PAROTIDECTOMY

Because mixed tumors of the parotid are usually so poorly delineated from the surrounding gland tissues and because they may be multicentric in origin (1, 15) we believe that attempts at enucleation of the tumor will result in continued high recurrence rates. For these reasons we have decided to treat some of the patients with tumors of the superficial lobe

of the parotid with superficial lobectomy, and in the remainder a total parotidectomy will be done. It is hoped by observing the recurrence rate in both groups that an answer will be available as to the best method of treating the superficial tumors.

Patients with tumors of the isthmus and deep portion of the gland should have total parotidectomies, similarly, if there is any suspicion as to the presence of malignant degeneration of the tumor, a total parotidectomy should be done.

CASE REPORTS

CASE 1 A K, No 736705, a white female, 56 years of age, was first seen in the outpatient tumor clinic at the University Hospital on October 28, 1946, complaining of two masses just behind the angle of the mandible on the left side, of 3 months' duration. These masses had grown steadily but slowly until they collected to form one and had caused patient intermittent moderately severe pain, particularly on opening and closing of the jaws. Examination revealed a mass about 2 by 3 centimeters just behind the angle of the left mandible, with an irregular firm surface and well defined nodular border. The tumor was moderately tender. There were no enlargements of the left cervical nodes and the chest plate was negative for metastases. The clinical impression was mixed tumor of the left parotid. On December 30,

Fig 4, left A K, 3 months after left total parotidectomy
Fig 5 Same patient Note intact junction of facial nerve

1946, a left total parotidectomy was done. The exposed tumor was ill-defined and appeared to be multinodular. It would have been very difficult to enucleate the tumor because of its apparent multinodular character. The pathological examination revealed the superficial portion of the parotid to be almost completely replaced by multinodular tumor with the largest nodules measuring up to 1.5 centimeters. Microscopic sections revealed the tumor to be composed chiefly of epithelial cells arranged in cords separated by hyaline connective tissue. In one or two areas were gland-like structures containing a mucous material in the center. The pathological diagnosis was cylindromatous type of mixed tumor. Following operation there was a temporary paresis of the muscles about the mouth which lasted for about 2 weeks. This patient was last seen on February 26, 1948. Examination revealed no evidence of recurrence and complete return of the facial nerve function (Figs 4, 5).

CASE 2 R W, No 776033, a white male, 35 years of age, was first seen at the University Hospitals, on February 26, 1947, complaining of a small mass beneath the right ear which had been present for about 25 years. During the 6 months prior to his hospital visit the tumor had increased in size, slowly but definitely, and in addition he noted pain down the right side of the neck. He also stated that he had noticed slight numbness of the right side of the face and slight asymmetry of the right corner of the mouth. Biopsy of the lesion by his doctor about 3 weeks prior to his admission to the University Hospitals resulted in a pathological report of mixed tumor of the parotid. Examination revealed a single mass, 3 by 4.5 centimeters, submandibular sub-auricular space with a recent biopsy scar over the prominence of the tumor. The facial nerve was intact and the remainder of the physical examination was essentially negative. On February 27, 1947 a right total parotidectomy was done. The skin overlying the mass was also removed. The pathological report revealed a single circumscribed mass 2 by 5

Fig 6, left R. W, 17 months following right total parotidectomy
Fig 7 Same patient Note intact junction of facial nerve

centimeters in diameter in the superficial portion of the gland. Microscopically the tumor was of a mixed type composed chiefly of myxomatous tissue divided into coarse rounded lobules by slender strands of connective tissue. Throughout there were scattered epithelial cords. After operation the patient had slight paresis of the orbicular oculi muscle which lasted about 4 months. He was last seen on June 13, 1948, at which time there were no evidences of recurrence of the tumor, and the facial nerve function had returned completely (Fig 6, 7).

In addition to these 2 cases,¹ 4 patients had superficial lobectomies and 5 have had total parotidectomies, and in all individuals except one, the seventh cranial nerve has been spared. In one case with recurrent tumors the cervical branch of the facial nerve was inadvertently transected. These cases have been done too recently to warrant any comments concerning recurrences.

DISCUSSION

Our own anatomical dissections of the parotid gland confirmed the observations of McWhorter and led to the adoption of the surgical technique described. McCormack, Cauldwell and Anson also suggested from their dissections that parotidectomy could be done by starting at the anterior aspect of the gland. Sistrunk in 1921 and Adson and Ott in 1924 suggested the identification of the intramandibular branch of the facial nerve as the starting

¹Since this paper was submitted for publication 11 additional patients have had superficial lobectomies and 9 have had parotidectomies.

point for removal of the parotid gland without injury to the facial nerve. Like H. Bailey (2) we have found it has been difficult to identify this branch readily in all patients.

Hamilton Bailey (2, 3) has also been a strong advocate of adequate exposure of the parotid gland before an attempt to remove the tumor is undertaken. He begins his dissection of the superficial lobe of the parotid at the lower anterior border of the gland. The main trunk of the facial nerve is identified posteriorly with the digastric muscle as a guide. Janes advocates identification of the stem of the facial nerve soon after it leaves the stylomastoid foramen. However, the depth of the stylomastoid foramen makes this approach to the facial nerve more difficult than the one described in this paper, where identification of the nerve fibers is made where they are superficial.

Parotidectomy performed by the technique described above is admirably suited for dealing with mixed tumors of the parotid. There is no question of trying to determine the extent of the tumor, of violating the pseudocapsule, and of injury to the facial nerve. Further, if there are multiple small tumors, as was present in one of the cases reported, or if there is a possibility of multiple foci of origin of mixed tumor as suggested by Ewing, total parotidectomy should result in a marked decrease in recurrent growths following surgery. The validity of this contention can be established only with the passage of time, for as McFarland pointed out, the average interval before recurrence after surgery was approximately 7 years, although a goodly number of recurrences appeared within a year of surgery.

By defining the anterior border of the gland, then dissecting posteriorly between it and the facial nerve the only part of the gland substance that is entered is the thin isthmus. This technique is used to facilitate the dissection. However, if the tumor occupies the isthmus, the transection of this part of the parotid is avoided and the whole gland is removed intact. This technique results in more handling and trauma to the facial nerve with a consequent longer period before recovery of its functions occurs.

Radical excision of the superficial portion of a parotid or a total parotidectomy should be

considered for all solid tumors of the gland, for these neoplasms should be assumed to be malignant until proved otherwise. On reviewing pathological sections of 210 parotid tumors at the Mayo Clinic, Quattlebaum and co-workers found 21 instances in which a previous diagnosis of a typical mixed tumor was reversed to adenocarcinoma of the cylindroma.

SUMMARY

1 The high recurrence rate following excision of parotid tumors is due primarily to inadequate excision of the tumor.

2 The lack of a true capsule and the myxomatous type of tissue of the tumor makes it difficult to determine the true extent of the neoplasm.

3 Fear of injury to the facial nerve also makes for inadequate conservative excision of parotid tumors.

4 The possibility that parotid tumors may be multiple or arise from multiple foci in different portions of the gland is also suggested as a possible cause of the high recurrence rate.

5 Radical excision of solid parotid tumors is also recommended because they may be malignant.

6 A surgical technique of superficial lobectomy of the parotid and total parotidectomy without injury to the seventh nerve is described.

THE TREATMENT OF CARCINOMA OF THE VULVA

CARCINOMA of the vulva is not a clinical entity. At some unknown time long ago the custom was established of including under this term carcinoma of the glans clitoris, of Bartholin's gland, some other glandular tumors and, occasionally, melanosarcoma of the vulva, along with the more common epithelioma of the labia, adjacent perineum, and vestibule. These represent such a variety of lesions from almost all points of view that there would seem to be no justification for grouping them together. There are, however, two reasons for continuing the tradition. Therapy has been similar throughout the group though yielding different degrees of effectiveness. The common epithelioma makes up an overwhelmingly large proportion of the total tumors so that inclusion of the special tumors has not seriously interfered with the expression of results. They may then be considered as a group in the present discussion of treatment.

Carcinoma of the vulva has been a relatively rare disease. But since it is characteristically a disease of advanced age, an increasing number may be expected as the age of the population increases. In general, use is not being made of knowledge and experience, the application of which has been demonstrated to improve very significantly the end results. For these reasons, it would seem wise to try to reach an understanding as to the problems, the attack, and the rewards in this condition. The object of this discussion is to demonstrate the applicability, effectiveness and safety of single stage radical vulvectomy under local anesthesia and to urge the acceptance of it as the standard method of treatment.

An astonishing variety of combinations of treatment forms has been applied to vulva carcinoma. At the University of Minnesota from 1928 through 1938, there were approximately half as many such combinations used as there were patients treated. This yielded a five year cure rate of 15 per cent. No single stage radical vulvectomy was done during this time but all manner of combinations of simple vulvectomy, gland resection, x-ray, surface and interstitial radium were used. Such excessive individualization of therapy can mean only that none of it was satisfactory, and the result produced would seem to confirm this. Anyone who has studied such clinical material will have little difficulty in arriving at the conclusion that simple vulvectomy is not an effective method of treatment. Irradiation is not even useful as a palliative procedure. Adequate depth doses cannot be obtained without destroying the skin of this sensitive area. And the tumor is radioresistant. While no standard arrangement of the two stage combina-

tion of vulvectomy and bilateral gland resection was applied in this material, the combination as it was carried out was not sufficiently effective to recommend it

One gets the impression that three attitudes have brought about the decision to undertake minor forms of treatment. Many of the patients are old and there is a very natural fear of the surgical risk involved. The poor results of minor therapy in these have been observed and the conclusion drawn that the disease is relatively incurable. And finally, too much importance has been ascribed to the problem of obtaining primary healing of the wound in the more extensive dissection of the single stage procedure.

On the other hand, the single stage radical removal of the vulva together with the inguinal and femoral glands in one intact piece has many attractions. It satisfies the generally applicable basic principles of surgical attack on malignant disease. Dissection is carried out in healthy tissue without cutting into the tumor or its lymph drainage area. This latter is removed intact to a point beyond which extension of the surgery will add more to the mortality of the procedure than it will to the cure rate. Bilateral gland removal is always done since it has proved impossible to determine accurately by clinical examination the presence or absence of gland metastasis, and since contralateral metastasis is frequent. The poor results shown to follow lesser procedures recommend the radical approach.

And now let us see what can be done with this radical approach. If it is to be useful, it must have a wide applicability, be reasonably free of serious after effects, produce a real increase in the cure rate and have a reasonably small primary procedural mortality. Ten years ago the department of obstetrics and gynecology at the University of Minnesota Medical School set out to study these prob-

lems. Only single stage radical vulvectomy under local procaine and adrenalin anesthesia was used in treatment. Except for minor variations in technique, this has not been changed during the period of study. The results have been reported in detail elsewhere. Every patient was included, whether she had been previously treated or not. Many had practically hopeless recurrences when first seen. A number had been refused treatment as hopeless by competent gynecologists. Some of the five year cures were derived from this latter group.

In more than 90 per cent of the patients, single stage radical vulvectomy was carried out. Four were not so treated because of extensive metastases above the inguinal and femoral gland groups. One refused treatment and one had no demonstrable tumor on biopsy or on examination of the simple vulvectomy specimen by two departments. It was found later as a microscopic tumor when the specimen was being completely cut for other purposes. No patient was excluded from surgery because of the local extent of the tumor or because of other physical abnormality. The applicability of the procedure is then practically complete where any reasonable hope of recovery exists. One is satisfied that the largest single factor in this degree of applicability lies in the use of local anesthesia.

No serious after effects have been seen. Occasionally edema of one or both legs may be present, particularly in obese women, for some time after operation. This has never been more than a nuisance. The local scar has not produced trouble.

More than 50 per cent of these patients were alive and free of tumor after five years. In view of the fact that a large proportion of these patients had advanced or recurrent tumor and many were very elderly, this cure rate would lead to the conclusion that carcinoma of the vulva ranks among the best of the

human cancers in its response to adequate therapy. Indeed, given a patient with a reasonable life expectancy and a reasonably early tumor which has not been tampered with, radical vulvectomy offers an excellent probability of permanent cure.

What operative mortality price was paid for this? Six per cent of the patients operated upon died before discharge from the hospital. None of these died in immediate association with the surgical event. One very old lady simply faded away some weeks after surgery and even autopsy failed to show a definite cause. One, who had a complete heart block before operation eventually died of this. One with a known preoperative pyelonephritis underwent a flare-up of this and died as a result. Two deaths were caused by pulmonary emboli. This does not seem to be too great a price to pay for the results achieved.¹

It would seem fair to conclude that single stage radical vulvectomy under local anesthesia routinely applied as early as possible but irrespective of the earliness or lateness of the local tumor and almost irrespective of the age or general physical status of the patient, offers the opportunity of reasonably safely increasing by three to five fold the salvage rate of lesser procedures sometimes used in the treatment of carcinoma of the vulva.

JOHN L. MCKELVEY

STREPTOMYCIN IN SKELETAL TUBERCULOSIS

AS clinical data accumulate, it is evident that streptomycin and its derivatives are really effective weapons for use in the treatment of tuberculosis of the bones and their allied structures. Tuberculosis, a slow unrelenting process, must be observed

for prolonged periods in order to determine its progression or arrest. This is especially true of tuberculosis in and about bones; therefore, these observations are being made with caution on tuberculosis of bones and joints.

It has been pointed out many times that when a therapeutic agent is carried to its desired destination by the blood stream, it does its best work if this region is flushed with blood. To date the best results from use of streptomycin in the treatment of tuberculosis of bones and allied structures have been in early tuberculosis of the soft tissues and synovia before bony involvement or soft tissue fibrosis has developed. At this time, frequently, the diagnosis is in doubt, but it should be proved by biopsy, culture, and animal inoculation. In several proved cases of synovial tuberculosis, a second biopsy after a course of streptomycin therapy has been negative for tuberculosis. The clinical results have been just as dramatic and what appears to be a cure has been effected. Fulminating open lesions of the extremities have been seen to return to a nearly normal status after a course of treatment with streptomycin. In the past many tuberculous sinuses and bursae were excised and cured without streptomycin, but with streptomycin as an adjunct complete and thorough excision of these lesions now can be done with greater assurance of healing.

Tuberculous lesions of the shafts of long bones are sufficiently rare, so that, as far as I know, no experience has been gained in their treatment with streptomycin.

The treatment of tuberculosis of joints presents two distinct problems. In a weight bearing joint where the demand is for a nearly normal structure which can maintain its function without mechanical flaws, the problem is more difficult than in a nonweight bearing joint where the demand on the joint is not so exacting. In the weight-bearing joints it

¹For further details reference is made to the *American Journal of Obstetrics and Gynecology*, 1947, 54: 676 and to the multiple reports of Taussig.

especially is important, then, to make an early diagnosis and institute treatment while the infection is still limited to the synovia and cartilaginous margins of the joint. When the diagnosis is made thus early, these joints have been and can be salvaged and their function retained. There are decided opinions as to whether joints of this sort should be immobilized during treatment. Traditionally, rest is indicated for the cure of tuberculosis. Practically more hyperemia and active dispersal of the streptomycin throughout the joint and its adjacent structures may occur when active motion without weight bearing is allowed. In cases which I have observed personally, the joint has been less stiff after treatment is stopped if it is allowed to be mobile during treatment. Obviously, streptomycin can be considered only an adjunct to surgical treatment when the articular surfaces are sufficiently destroyed so that even if the tuberculosis were arrested, traumatic arthritis would be present. It seems to me, however, that a preoperative course of treatment with streptomycin has allowed excision and arthrodesis in cases of fulminating tuberculosis of the joints in which the chances of success without it were slight. In the past amputation would have been necessary in many of these cases. Treatment with streptomycin also seems to have lessened the danger of disseminated tuberculosis and persistent draining sinuses and mixed infections do not appear to be as common before operation as formerly.

In lesions of the nonweight-bearing joints, it does not appear that arthrodesis will need to be recommended as frequently as it was when streptomycin was not available. This statement is made with some reservations because, in cases of extensive fibrotic and sclerotic tuberculosis about these joints a period of arrest followed by reactivation in a year or two has been noted. This reactivation may

or may not be controlled by a second course of streptomycin. The danger of appearance of strains of tubercle bacilli resistant to streptomycin has to be considered in these cases. Experience is not great enough, as yet, for anyone to know whether streptomycin should be considered an adjunct to surgery or as a complete therapeutic agent for tuberculosis of these joints. It is possible that, at present, with the more conservative attitude, we are missing the golden opportunity to succeed with arthrodesis. We will have to await the lesson of experience.

Solutions of streptomycin have been injected into the joints but the drug appears to be somewhat irritating. Clinical experience has shown, however, that effective concentrations can be obtained within the joint by intramuscular injection.

Tuberculosis of the spinal column presents a somewhat more difficult problem of analysis. Even when roentgenograms are good, critical evaluation of destruction and repair can vary within broad bounds. Conclusions on results must be slowly formed because of the nature of the disease and the nature of bone repair itself. Thus far, preliminary surveys are mildly favorable. If the disease is fairly advanced and was discovered late, too startling a result cannot be expected. The disease is serious enough so that all modes of treatment, including streptomycin, are being used. Rest and spinal fusion in the past effected cures so that everyone concerned must be cautious about giving too much credit to streptomycin. I believe, however, that it facilitates the process of healing.

The exact place of streptomycin in the treatment of tuberculosis of bones and allied structures is not known as yet. At the end of the next decade of study its place should be evaluated better than at present.

WILLIAM H. BICKEL

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE fourth book in the series *British Surgical Practice*¹ begins with the subject of "Facial Palsy" and ends with "Hiccup."

The editors have adhered closely to their original promise to select authorities in each field and to permit each author to develop his topic without interference. Subjects are listed in alphabetic order entirely, so there is no central theme for any one volume. Concise review of the entire volume is therefore impossible, but certain features are outstanding and deserve comment.

Many of the topics in the present volume might be considered decidedly nonsurgical in scope, for example, filariasis, frostbite, gonorrhea, gout, and herpes zoster, and the casual observer might feel that for the sake of brevity many of these could be omitted. However, the set of volumes includes at least brief references to many situations which will confront the doctor, especially one who is in a remote community. The delightful style apparent in the first 3 volumes is still a feature and makes pleasant reading.

The discussion of facial palsy emphasizes injuries to nerves likely to occur in performing radical mastoidectomy. The illustrations are excellent, the outline method of presentation is convenient, and the general discussion is adequate. The enthusiasm of the author of this section for various procedures leads the reader to feel that operations, such as nerve crossing and anastomosis, are attended by far happier results than certain American authorities have achieved.

The chapter on maxillofacial injury is clear and concise. Most of the present knowledge on this subject is included, although the references are a bit brief. It is interesting to note that in the discussion of treatment of fracture of the jaw space is devoted to the use of multiple pins for external fixation. It seems somewhat surprising that there is so little mention of war injuries. Complications and post-operative care could well have received more detailed discussion.

A fascinating chapter on fascial grafts by no less an authority than Professor Gallie presents the background for use of fascia as a living or nonliving suture, and there are excellent illustrations of the proper application of the suture. The convenience of the Masson stripper is emphasized. The reviewer

realizes that the use of fascial grafts may become a lost art if the young surgeon of today does not master the technique required for successful use of this valuable aid because so many foreign substances, such as wire, screen, and mesh gauze, are now being used to supplant fascial grafts. Professor Gallie's chapter is most timely in that regard.

The miscellaneous chapters on fields of greater or lesser surgical interest will probably be of use to a limited group of surgeons. A long and complete outline on surgery of the foot is outstanding, and the diagrams and illustrations are very practical, they will probably be used widely as an authoritative reference for the busy practitioner. Other chapters deal with orthopedic problems including those of the upper extremity, clavicle, femur and some of the smaller bones. It is noteworthy that considerable space is devoted to the use of appliances and splints, and relatively little comment is directed toward open operation with internal fixation which is used extensively in many centers today.

One of the most valuable chapters is the one dealing with the gall bladder and bile passages. A convenient outline presents briefly the historical background where indicated and, at the same time, brings the reader up to date on many of the newer concepts. The portion dealing with acute cholecystitis is in complete accord with leading surgical thought in America. Warnings are sounded at the proper places and pitfalls and safeguards are stressed properly. Each feature is catalogued in alphabetic sequence and, although brevity is the keynote of the chapter, completeness is one of its strong points. The American surgeon will note with interest the discussion on acquired stricture of the common bile duct. Recently, American specialists in internal medicine have tended to point to Great Britain because it seemed that tragedy of this type was almost unheard of there. However, British surgeons apparently still do encounter an occasional case and have just as much difficulty with this problem as American surgeons have. It is noteworthy that the author predicted a brilliant future for those patients who had undergone reconstruction of the common bile duct over vitallium tubes. It may not be common knowledge but the fact remains that the use of vitallium tubes has been met with almost universal failure because they become plugged. Little is included concerning the Whipple operation and its modifications. The assumption is that a subsequent volume will contain more discussion of malignant lesions in the biliary system.

¹BRITISH SURGICAL PRACTICE. Under the general editorship of Sir Ernest Rock, Carling, FRCS, FRCP, and J. Patterson, Ross, MS, FRCS, Vol. 4. London: Butterworth & Co. Ltd. St. Louis: The C. V. Mosby Co. 1943.

The chapter on gas gangrene follows a logical sequence, namely, a comparison of the experiences in World War I with those in World War II. It is of interest that the author felt that penicillin might change the entire picture of this dread complication. The consensus now is that penicillin has been of little or no value in the treatment of patients who have gas gangrene, at least this proved to be true in the series of cases observed in the American army in the Pacific area.

One reads with mixed opinions the chapter on gland puncture and aspiration biopsy. This seems to be a controversial topic throughout the civilized world today. Although most of the points that the author makes are undoubtedly true and the illustrations he presents are excellent, many American authorities hold this technique in a questionable light. They feel that for biopsy removal of actual tissue with the scalpel is a thorough and less dangerous method. Many surgeons in America endeavor to supply the pathologist with an adequate amount of tissue for a final opinion and feel that this method is more satisfactory than obtaining the specimen for biopsy with the needle. In the United States there has been an evolution from obtaining a specimen of the liver for biopsy by needle. Two years ago the great enthusiasm for this method led to the inevitable situation hemorrhage was encountered which required laparotomy for control. In scattered reports it has now been learned that in a few cases this type of biopsy has resulted in death of the patient.

Some miscellaneous topics are of considerable interest if only because of the knowledge that the data are available for ready reference in this volume. The chapters concerning gunshot wounds are rather too brief, inasmuch as the average reader of these volumes will undoubtedly be in a position to require considerable information on the proper management in this type of case. Strangely enough, more space is devoted to reconstructive surgery than to acute injuries. The same criticism might apply to this volume which was offered in previous volumes, namely, that patients requiring reconstructive surgery might profit greatly if they were referred to special centers where proper definitive treatment could be carried out.

The detailed discussion of hernias is indeed timely, as the tremendous advances in surgery might lead the young surgeon to overlook this type of lesion. Thorough understanding of the primary situation should reduce the necessity for much experience with recurrent hernias. This part of this volume is one of the most valuable of all.

The volume ends with a short chapter on hiccup. Evidently this is as much of a problem in the British Isles as it is in the United States and the variety of methods used in attempts to overcome this distressing condition is testimony to the obvious fact that there is no reliable method. Brief comment is made about interruption of the phrenic nerve with the conclusion that "this can rarely be justified."

E S JUDD, JR

THE fourth edition of the *Manual of Urology*¹ by Ralph M. LeComte is a valuable contribution to the field of urologic literature.

The author has tried to write for the student beginning the study of urology. This aim has been achieved, and the simplicity of the text is one of its most outstanding features. It should be in the hands of every senior medical student.

That portion of the text dealing with infections of the urinary tract is as up to date as it can possibly be. The material on chemotherapeutic agents and antibiotics is authoritative and is clearly written.

It is of interest to notice how the author handles such controversial material as nephropotosis and ureteral stricture. His words are certainly conservative.

He believes that all diagnostic procedures and all other therapeutic procedures should be carried out carefully before considering nephropexy. Likewise, he feels that, while a ureteral stricture certainly may occur, its frequency is not as great as formerly believed, and the symptoms it causes are not as legion as previously considered.

One of the best sections in the book is that concerning the treatment of benign prostatic enlargement. The author considers all sides of this problem and then gives his own opinion. He favors open operation except in cases of small enlargement and cases of fibrosis of the vesical neck. In these cases, he believes that transurethral resection definitely is indicated.

The chapter on impotence and sterility in the male should be read by all practicing urologists and should benefit the general practitioner as well.

THOMAS L. POOL

IN the volume *Principi di chirurgia del cervello e del midollo spinale*² (Principles of Surgery of the Brain and Spinal Cord), Africo Serra deals mostly with the surgical technique devised by Cushing, de Martel, Fedor Krause, Olivecrona, Elsberg, Frazier and their predecessors. Few of the recent advances are described or even mentioned in this book. The most important chapters deal with the subtemporal and suboccipital decompressions, the puncture of the corpus callosum for decompressive purposes, the frontal, frontoparietal and parieto-occipital craniotomies for the removal of tumors or the cure of jacksonian epilepsy, the different types of craniotomies of the posterior fossa, the temporal craniotomy for the relief of trigeminal neuralgia and the laminectomies. In 2 long, and perhaps the most interesting chapters, the author discusses the postoperative courses of the various types of brain tumors and their complications. He pays a great deal of attention to the influence of cerebral edema. The action of disturbances of the mesencephalic medullary centers on the centers of respiration, blood circulation, and

¹MANUAL OF UROLOGY. By R. M. LeComte, M.D. F.A.C.S. 4th ed. Baltimore: The Williams & Wilkins Co., 1948.

²PRINCIPI DI CHIRURGIA DEL CERVELLO E DEL MIDOLLO SPINALE. By Africo Serra. Bologna: Licio Cappelli, 1948.

heart is illustrated by interesting case reports and is discussed from anatomical points of view.

Shorter chapters deal with interventions on the lateral and the third ventricles, however, the widely used Torkildsen procedure is completely ignored. The treatment of spastic torticollis is the one devised by Dandy and Olivecrona. The surgery of intracranial aneurysms is only briefly mentioned and the author states that he had only one such case. He also fails to mention the treatment of brain abscess, intracranial and intracerebral hematoma, hydrocephalus, platybasia, etc. He does not discuss any diagnostic studies, or the management of cranio-cerebral injuries.

The great value of the book lies mostly in the beautiful illustrations and especially the excellent colored drawings of operative fields and anatomical dissections made by the author himself. It also contains a large number of operative photographs showing the major steps in the various types of craniotomies. This 569 page book contains 401 text illustrations and 52 plates.

GEORGE PERRET

THE author of *Bronchogenic Carcinoma and Adenoma*¹, B. M. Fried, has drawn on the extensive experience of the Division of Chest Diseases of the Montefiore Hospital in New York and on the surgical literature in preparing this monograph.

¹BRONCHIOGENIC CARCINOMA AND ADENOMA WITH A CHAPTER ON MEDIASTINAL TUMORS. By B. M. Fried, M.D. Baltimore: The Williams & Wilkins Co. 1948.

The chapters on the medical aspects of carcinoma of the bronchus are adequate and are profusely illustrated with pictures of gross specimens, photomicrographs, and reproductions of roentgenograms of the chest. In contrast, the treatment of the condition is covered inadequately, only 3 pages being devoted to the discussion of the surgical treatment. The same criticism might be applied to the chapter on adenoma of the bronchus, the treatment of which is discussed briefly in one-half page.

The questions of alveolar cell carcinoma and adenomatosis of the lungs are discussed together in a special supplement although there is no evidence that there is any relation between them. The author takes the dogmatic stand that alveolar cell carcinoma does not occur, attributing the condition to canalicular metastases from an invisible or overlooked carcinoma of the bronchus.

There is a lengthy discussion of the coincidental occurrence of carcinoma of the bronchus and pulmonary tuberculosis in the same patient. Another chapter is devoted to hypertrophic pulmonary osteoarthropathy which the author suggests is due to a "disturbance in the function of the organs of internal secretion." There is a final chapter on mediastinal tumors but this is incomplete and is of questionable value in this book.

Although the book is a worthwhile addition to the literature on carcinoma of the bronchus it does not satisfy the need for a complete review of our present knowledge about the condition. DAVIN CARR

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

DALLAS B PHEMISTER, Chicago, *President*
FREDERICK A COLLER, Ann Arbor, *President-Elect*

PRELIMINARY PROGRAM FOR THE 35th CLINICAL CONGRESS—THE STEVENS, CHICAGO OCTOBER 17 TO 21, 1949

ALWAYS an outstanding international event, the Clinical Congress of the American College of Surgeons will in 1949 be exceptionally world-wide in representation because it will include the Sixth Inter-American Congress of Surgery and because many delegates from the thirteenth Congress of the International Society of Surgery which meets in New Orleans the previous week are planning to attend the Chicago Congresses. The Sixth Inter-American Congress of Surgery will actually be a seven-day meeting, extending from October 17 through 23, since it is meeting concurrently with the Clinical Congress of the American College of Surgeons and will continue in session two days after its close. Headquarters for both meetings will be at The Stevens.

Through the membership of the American College of Surgeons in the Association of Inter-American Congresses of Surgery, every Fellow is a member of the latter group and is entitled to attend its scientific and social sessions on Saturday and Sunday. The members of the signatory societies of the Association are likewise entitled to attend the Clinical Congress clinics and sessions. These facts should be borne in mind in making hotel reservations. The Inter-American Congress offers an excellent opportunity to enhance the international prestige of the American College of Surgeons, as well as to familiarize North American Fellows and overseas guests with surgical progress in the other Americas.

Preliminary plans for the Sixth Inter-American Congress of Surgery are described in a separate article which follows. It will be noted that the inaugural session, open to delegates only, will be held on Friday morning, October 21. The scientific sessions on Saturday and Sunday, and the official banquet on Saturday evening, are open to

all Fellows, whose presence will help to demonstrate how deeply interested the American College of Surgeons is in the cultivation of mutually beneficial professional and social relationships among surgeons throughout the Americas.

PRELIMINARY PROGRAM

A varied and comprehensive program of meetings will be held at the headquarters hotel. A general assembly for both surgeons and hospital personnel will be the opening session on Monday morning, October 17. Scientific sessions, official meetings, hospital conferences, showings of medical motion pictures, and telecasts will follow during the five days of the Clinical Congress. The special sessions of the Sixth Inter-American Congress of Surgery on Friday, Saturday, and Sunday, will, according to present plans, be held in the John B. Murphy Auditorium of the College. All registrants for both Congresses will be interested in the extensive display of technical and scientific exhibits in the exhibition hall.

CLINICS

Operative and nonoperative clinics will be held in some twenty hospitals in the Chicago area each day during the Clinical Congress. The hospitals which will participate in the clinical program, and which are listed later in this article, are approved by the American College of Surgeons for graduate training in surgery. The schedule of clinics, which will cover general surgery, obstetrics and gynecology, fractures and other traumas, orthopedic surgery, thoracic surgery, plastic surgery, neurosurgery, genitourinary surgery, and ophthalmology and otorhinolaryngology, will be published in a *Daily Clinical Bulletin* which will be issued each day during the Clinical Congress. The clinic schedules will also be posted on bulletin boards.

TELEVISION

Operations will be telecast, in color, to the hotel from St. Luke's Hospital at scheduled periods each day. The television program will be over a closed circuit, impossible to pick up on public sets. The operations and demonstrations will be transmitted to about twenty color transmission receivers in the hotel. The engineers anticipate excellent reception since the hospital is in a direct line of vision from the roof of The Stevens. The television will be sponsored by Smith, Kline & French Laboratories.

The successful demonstrations of television at the Clinical Congress in New York in 1947, and at the Clinical Congress in Los Angeles in 1948, make it highly desirable to continue the use of this medium. Even when limited to black and white images, as it was then, the surgeons were most enthusiastic.

Television has proved to be an ideal means of furthering the "Show me" purpose which was the main incentive for the founding of the Clinical Congress of Surgeons of North America in 1910, three years before the American College of Surgeons was organized. That first Clinical Congress was held in Chicago. The 1949 meeting will be the ninth held in that city.

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening, October 17. At this meeting the officers-elect, consisting of Dr. Frederick A. Collier of Ann Arbor, president, Dr. Donald G. Tollefson of Los Angeles, first vice-president, and Dr. Robert M. Moore of Galveston, second vice-president, will be installed. The outgoing president, Dr. Dallas B. Phemister of Chicago, will preside and will deliver the Presidential Address. His subject will be "An Evaluation of Fulltime and Group Practice for the Clinical Faculty of a Medical School."

Sir James R. Learmonth of Edinburgh will deliver the fourth Martin Memorial Lecture. His subject will be "Collateral Circulations, Natural and Artificial."

CONVOCATION

The formal initiation ceremonies for the new Fellows will be a colorful feature of the annual Convocation which will be held on the final evening, Friday, October 21. Honorary fellowships will also be conferred on this occasion. Lord Webb-Johnson of London, president of the Royal College of Surgeons of England, will deliver the Fellowship Address. His subject will be "Science in Surgery: Stop, and Look, and Listen."

EVENING SCIENTIFIC SESSIONS—
GENERAL SURGERY

The program and speakers for the Tuesday evening general surgery session will be as follows:

Symposium—Acute Surgical Emergencies in Gynecology and Obstetrics

General Introduction NEWELL W. PHILPOT, M.D., F.A.C.S., Montreal

Tubal Pregnancy, Its Diagnosis and Treatment LEWIS C. SCHEFFEY, M.D., Philadelphia

Pelvic Peritonitis Occurring in the Obstetrical or Gynecological Patient FRANK GIEN, M.D., F.A.C.S., New York

Emergency Cesarean Section WILLIAM L. STUDDIFORD, M.D., F.A.C.S., New York

The program and speakers for the Wednesday evening general surgery session will be as follows:

Fracture Oration: Fracture Hazards OTTO J. HERMANN, M.D., F.A.C.S., Boston

Symposium—Blood Coagulation and the use of Anticoagulants

The Significance of Different Methods for Prothrombin Estimation and their Relative Values JOHN H. OLWIN, M.D., Chicago

Studies on Antithrombin and Etiologic Factors in Phlebothrombosis JOHN H. KAY, M.D., New Orleans

A Further Report on Dicumarol Prophylaxis against Venous Thrombosis in Women Undergoing Surgery GEORGE VAN S. SMITH, M.D., F.A.C.S., Brookline, Massachusetts

The program and speakers for the Thursday evening general surgery session will be as follows:

Symposium—Malignant Disease

Chemotherapy in Malignant Neoplastic Disease CARL V. MOORE, M.D., St. Louis

Hormone Therapy of Cancer CHARLES H. HUGGINS, M.D., Chicago

The Use of Radioactive Iodine in Studying the Pathologic Physiology of Thyroid Cancer RULON W. RAWSON, M.D., New York

What We Have Learned from Isotopes Concerning Depletion and Repair in Surgical Patients FRANCIS D. MOORE, M.D., F.A.C.S., Boston

GENERAL SURGERY PANEL DISCUSSIONS

General surgery panel discussions will be held on Monday, Tuesday, and Wednesday afternoon from 1:30 to 3:00 and from 3:30 to 5:00 p.m. The subjects and the names of the members will follow.

Monday—1 30 to 3 00 p m

Surgical Lesions of the Breast GEORGE G
FINNEY, M D , F A C S , Baltimore

3 30 to 5 00 p m

Fractures of the Skull ELDRIDGE H CAMPBELL,
M D , F A C S , Albany

Tuesday—1 30 to 3 00 p m

Massive Upper Abdominal Hemorrhage JOHN H
MULHOLLAND, M D , F A C S , New York

3 30 to 5 00 p m

New Surgical Techniques in Drug Treated Infec-
tions CHAMP LYONS, M D , New Orleans

Wednesday—1 30 to 3 00 p m

The Management of Acute Emergencies Occur-
ring During Operations I MIMS GAGE, M D ,
F A C S , New Orleans

3 30 to 5 00 p m

Preoperative and Postoperative Care and Anes-
thesia for Infants THOMAS H LANMAN, M D ,
F A C S , Boston

SPECIAL FIELDS OF SURGERY

Friday 1 30 to 4 45 P M

On Friday afternoon there will be panel discus-
sion sessions for six special fields of surgery as
follows

Orthopedic Surgery

GUY A CALDWELL, M D , F A C S , New Orleans,
Moderator

1 30 to 3 00 p m

Management of Established Non-Union of the
Long Bones

3 15 to 4 45 p m

Indications and Technique for Arthrodeses of the
Joint of the Foot and Ankle in Post-traumatic
Conditions

Plastic Surgery

JEROME P WEBSTER, M D , F A C S , New York,
Moderator

1 30 to 3 00 p m

Plastic Surgery and the Treatment of Malignant
Skin Disease

3 15 to 4 45 p m

Indications be Broadened?

OPHTHALMOLOGY AND OTOLARYNGOLOGY

On Tuesday, Wednesday and Thursday sepa-
rate programs are being planned for specialists in
each of these two fields of surgery Special em-
phasis will be given this year to hospital operative
clinic programs The detailed programs for the
Ophthalmology section and for the Otolaryn-
gology section will be announced later

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems
will be held on Monday through Thursday after-
noons, and Tuesday through Friday mornings
Brief reports of original clinical and experimental
observations relating to the broad aspects of sur-
gery and the surgical specialties will be presented,
under the general direction of Dr Owen H Wan-
gensteen, chairman of the committee, Forum on
Fundamental Surgical Problems

The Thursday afternoon session will be conducted by Dr I S Ravdin of Philadelphia as a seminar on "Nutritional Problems Including a Consideration of Fluids and Electrolytes"

SYMPOSIUM ON CANCER

On Wednesday afternoon, from 2 00 to 5 00 o'clock, a Symposium on Cancer will be held. Speakers will include Dr Hamilton Montgomery, of Rochester, Minnesota, Dr Murray M Copeland, of Washington, D C, Dr Herman L Kretschmer, of Chicago, Dr Arthur Purdy Stout, of New York, and Dr Hayes Martin, of New York. Dr Grantley W Taylor, of Boston, chairman of the Cancer Committee, will preside.

SYMPOSIUM ON TRAUMA

An interesting program for the Symposium on Trauma on Tuesday afternoon, from 2 00 to 5 00 o'clock, is being developed under the direction of Dr Robert H Kennedy. Among the speakers will be Dr Mather Cleveland, of New York, Dr Harrison L McLaughlin, of New York, and Dr James Barrett Brown, of St Louis.

HOSPITAL CONFERENCES

The twenty-eighth Hospital Standardization Conference will be held during the first 4 days of the Clinical Congress. Its opening meeting will constitute the first formal session of the Clinical Congress and will be for both surgeons and hospital representatives. Dr Dallas B Phemister, president of the College, will preside.

Hospital administrators, trustees, members of medical staffs, nurses, technicians, dietitians, and heads of the various hospital departments and their personnel, are invited to participate in the discussions at the hospital conferences which will be directed by leading authorities in the hospital field in the United States and Canada. The program will include formal sessions, panel discussions, round table conferences, symposia, and forums.

COMMITTEE ON ARRANGEMENTS AND EXECUTIVE COMMITTEE

The Chicago Committee on Arrangements and Executive Committee for the Clinical Congress are actively at work on arrangements for the program. The membership of these Committees follows:

Committee on Arrangements

Warren H Cole, M D, F A C S, Chairman
Lester R Dragstedt, M D, F A C S, Vice Chairman
Michael L Mason, M D, F A C S, Secretary
Dallas B Phemister, M D, F A C S, President and Regent of the College

William E Adams, M D, F A C S
James J Callahan, M D, F A C S
Fremont A Chandler, M D, F A C S
Edward A Christofferson, M D, F A C S
Vernon C David, M D, F A C S
Loyal Davis, M D, F A C S
M Edward Davis, M D, F A C S
Paul W Greeley, M D, F A C S
Paul H Holinger, M D, F A C S
Sumner L Koch, M D, F A C S
Herman L Kretschmer, M D, F A C S
Walter G Maddock, M D, F A C S
Foster L McMillan, M D, F A C S
Karl A Meyer, M D, F A C S
Harry A Oberhelman, M D, F A C S
Willis J Potts, M D, F A C S
Charles B Puestow, M D, F A C S
Herbert E Schmitz, M D, F A C S
Derrick T Vail, M D, F A C S

Executive Committee

Warren H Cole, M D, Chairman
Lester R Dragstedt, M D, Vice Chairman
Michael L Mason, M D, Secretary
Dallas B Phemister, M D, President and Regent of the College
James J Callahan, M D
Loyal Davis, M D
Walter G Maddock, M D

PARTICIPATING HOSPITALS AND HOSPITAL CLINICS COMMITTEE

A list of the participating hospitals and hospital clinics committee follows:

Augustana Hospital, OSCAR I NADAU, M D, F A C S
Children's Memorial Hospital, PAUL I LON, M D, F A C S
Cook County Hospital, MANUEL I LICHTENSTEIN, M D, F A C S
Evanston Memorial Hospital, FREDERICK CHRISTOPHER, M D, F A C S
Illinois Eye and Ear Infirmary, MAURICE D PEARMAN, M D
Lewis Memorial Maternity Hospital, HERBERT I SCHMITZ, M D, F A C S

Auditorium of the College at the time of the Con-
gress in October

TECHNICAL AND EDUCATIONAL EXHIBITION
The Technical and Educational Exhibits will
be held in the Exhibition Hall on the lower level of
The Stevens There will be represented leading
manufacturers of surgical instruments, of x-ray
apparatus, of sterilizers, of operating room lights,
of ligatures, of dressings, of hospital apparatus and
supplies of all kinds, and of pharmaceuticals, and
publishers of medical books
There will also be presented exhibits depicting
the work of the College

SPECIAL COMMITTEE ON TELEVISION
Foster L McMillan, M D, F A C S, St Lukes Hospital,
Chairman
Burton C Kilbourne, M D
Charles E Shannon, M D, F A C S

GENERAL AND PROGRAM COMMITTEES
The Clinical Congress general committee which
operates under the Administrative Board of the
College, consists of Dr Malcolm T MacEachern,
chairman, Miss Eleanor K Grimm, secretary,
Doctors Bowman C Crowell, Charles F Branch,
George H Miller and H Prather Saunders, and
Mr Edward G Sandrok, Mr James S Shannon,
and Miss Laura G Jackson
The Clinical Congress Committee on Program
consists of Dr Frederick A Collier, chairman, and
Doctors Henry W Cave, Evarts A Graham, and
Alton Ochsner
The Advisory Committee on Programs consists
of Dr George H Miller, chairman, and Doctors
Warren H Cole, Sumner L Koch, Michael L
Mason, Charles B Puestow, Bowman C Crowell,
H Prather Saunders, Charles F Branch, and
Malcolm T MacEachern

MEDICAL MOTION PICTURES

The showing of medical motion pictures each
day will again be a popular feature of the Clinical
Congress The latest available films on surgery
and related subjects will be presented Special
showings will be arranged of medical motion pic-
tures in the fields of ophthalmology and otorhino-
laryngology Both sound and silent films will be
shown, all of which will have been approved by
the Committee on Motion Pictures

Some of the newer medical motion pictures
which have been or are being produced under
Directing Committees of the College, will be pre-
sented during the Clinical Congress Among these
will be the film entitled "Injuries of the Peripheral
Nerves" directed by Dr Loyal Davis, under a
grant from the Johnson & Johnson Research
Foundation A premiere showing of this particu-
lar film will take place in the Murphy Memorial

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress
should register in advance Advance registration
will greatly expedite the procedure of registering
No registration fee will be charged Fellows whose
dues are paid to December 31, 1948 For endorsed
Junior and Senior Candidates, the fee will be
\$5 00 Non-Fellows who after individual consid-
eration are permitted to register, will pay a fee of
\$10 00 No registration fee will be required of
initiates of the class of 1949

HOTEL RESERVATIONS

It is desirable to make hotel reservations as
early as possible In making these, communica-
tions should be addressed to the Convention
Housing Bureau, 105 West Madison Street,
Chicago, stating that you will be attending the
Clinical Congress of the American College of
Surgeons All hotel reservations, both for sur-
geons and hospital representatives, are to clear
through this Bureau No correspondence should
be sent directly to the hotels A form for reserva-
tions was enclosed in the letter recently sent to
Fellows Choice of hotels may be designated
A list of the principal participating hotels and
minimum rates follows

	Single	Double
Chicago Hotels	\$3 50	\$5 00
Atlantic	5 00	8 00
Bismarck	3 50	6 00
Brevort	3 75	5 50

SIXTH INTER-AMERICAN CONGRESS OF SURGERY

Chicago, Illinois, October 17 to 23, 1949

Separate Sessions—October 21, 22, and 23

THE Sixth Inter-American Congress of Surgery will meet as a part of the Thirty-fifth Clinical Congress of the American College of Surgeons from October 17 to 21, with headquarters at The Stevens in Chicago, and will continue on October 21, 22, and 23 with its own business, scientific, and social sessions, most of which will be held in the John B. Murphy Memorial Auditorium of the College at 50 East Erie Street.

The surgical societies of the following countries, in addition to the United States, are members of the Association of Inter-American Congresses of Surgery: Argentina, Bolivia, Brazil, Chile, Cuba, Ecuador, Mexico, Panama, Paraguay, Peru, and Uruguay. The American College of Surgeons joined the association by vote of the Board of Regents on June 27, 1943. This action was preceded by an invitation from Dr. Luis Vargas Salcedo of Santiago, Chile, to send two delegates as guests of honor to the First Inter-American Congress of Surgery, held in Santiago November 15 to 19, 1942. Dr. Leo Eloesser, of San Francisco, attended as delegate, and it was upon his enthusiastic recommendation that the College joined the association. He also attended the second Congress, in Buenos Aires, October 10 to 15, 1943. Dr. Alton Ochsner, of New Orleans, was delegate to the third Congress, in Montevideo, Uruguay, October 1 to 6, 1946. No delegates were sent to the fourth Congress, held in Rio de Janeiro in 1947. Dr. E. Payne Palmer, of Phoenix, and Dr. Hu Crim Myers, of Philippi, West Virginia, were delegates and co-relators at the fifth Congress, held in La Paz, Bolivia, October 17 to 21, 1948.

Dr. Frederick A. Collier, who will be inducted on October 17 as President of the American College of Surgeons, will, as President of the signatory society of surgeons in the host country, serve as President of the Sixth Inter-American Congress of Surgery. Dr. Arnaldo Caviglia, of Buenos Aires, is Secretary-General of the association, and will set up an office in Chicago prior to and during the meeting. The following committees will aid in the arrangements:

COMMITTEES ON INTER-AMERICAN RELATIONS,
AMERICAN COLLEGE OF SURGEONS*General Committee on Inter-American Relations*

IRVIN ABELL, Louisville, *Chairman*
ALFRED BLALOCK, Baltimore
FRANCIS P. CORRIGAN, Washington
LEO ELOESSER, San Francisco
RUDOLPH MATAS, New Orleans
OSCAR L. MILLER, Charlotte, N. C.
HOWARD C. NAFFZIGER, San Francisco
ALTON OCHSNER, New Orleans

Advisory Committee

FRANCIS P. CORRIGAN, New York, *Chairman*
JAMES T. CASE, Chicago
CHEVALIER L. JACKSON, Philadelphia
OSCAR L. MILLER, Charlotte, N. C.
HU CRIM MYERS, Philippi, W. Va.

WARREN H. COLE, Chicago
LESTER R. DRAGSTEDT, Chicago
MICHAEL L. MASON, Chicago
DALLAS B. PHEMISTER, Chicago

THE PROGRAM

A preliminary outline of the program for the Sixth Inter-American Congress of Surgery follows:

Friday morning, October 21

Inaugural Ceremony

Friday afternoon, October 21

Delegates may attend the specialty panels of the Clinical Congress

Saturday morning, October 22

Main Theme Acute Cramocerebral Trauma
Relator E JEFFERSON BROWDER, M D ,
F.A.C S , Brooklyn, New York, U S A
Co-relators To be appointed by each member
country

Saturday afternoon, October 22

Main Theme Treatment of Injuries in the Re-
gion of the Ankle with Complications and Se-
quelae
Relator HARRISON L McLAUGHLIN, M D ,
F A C S , New York, New York, U S A
Co-relators To be appointed by each country

Saturday evening, October 22

Official Banquet

Sunday morning, October 23

Business Session

Sunday afternoon, October 23

Main Theme Pulmonary Carcinoma
Relator EVARTS A GRAHAM, M D , F A C S ,
St Louis, Missouri, U S A
Co-relators To be appointed by each member
country

THIRTEENTH CONGRESS, INTERNATIONAL SOCIETY OF SURGERY

(Société Internationale de Chirurgie)

New Orleans, Louisiana, U S A , October 9 to 15, 1949

THE following announcement has been received from Dr L Dejardin, Secretary-General of the International Society of Surgery

Plans for the Thirteenth Congress of the International Society of Surgery, which will take place in New Orleans, Louisiana, under the Presidency of Professor George Grey Turner, of London, England, are now in course of preparation

The scientific program was settled by the General Assembly at the last Congress in London, held in September, 1947. This body, at the recommendation of the Scientific Committee, also accepted two additional subjects, and decided who should open each discussion. The final arrangements were as follows

- 1 Surgery and Pathology of the Pancreas, Especially in Relation to Its Endocrine Function. Opened by PROFESSOR IAN AIRD, London
- 2 Surgery of the Parathyroid Glands. Opened by DR PAOLUCCI, Rome
- 3 Surgery of the Suprarenal Glands. Opened by DR M R IONTAINE, Strasburg
- 4 Pathology and Surgery of the Pituitary Glands. Opened by DR M P MARTIN, Brussels
- 5 Treatment of Postoperative Thrombosis and Its Sequelae. Opened by DR ALTON OCHSNER, New Orleans, and DR. MICHAEL DE BAKEY, Houston
- 6 Causes of Recurrence after Operations on the Biliary Tract. Opened by DR. M R DEMEL, Vienna

In addition, the American Organizing Committee has arranged that two or three days of the meeting shall be devoted to the presentation of shorter papers on subjects of immediate interest

The complete program, both scientific and social, will be circulated in due course

The program is being formulated by Vice President Evarts A Graham, of St. Louis, Missouri

OFFICERS FOR THE BIENNIUM

GEORGE GREY TURNER, London, England, *President*
GORDON GORDON TAYLOR, London, England, *Vice President*

P MATHIEU, Paris, France, *Vice President*
R DOS SANTOS, Lisbon, Spain, *Vice President*
EVARTS A GRAHAM, St. Louis, Missouri, U.S.A., *Vice President*
SERGEI S YUDIN, Moscow, U.S.S.R., *Vice President*
J VERHOOGEN, Brussels, Belgium, *President of International Committee*
LEO A M DEJARDIN, Brussels, Belgium, *Secretary-General*
PAUL E LORTHOIR, Brussels, Belgium, *Treasurer*
G SPEHL, Brussels, Belgium, *Editor, "Journal International de Chirurgie"*
I MIMS GAGE, New Orleans, Louisiana, *Secretary of the 13th Congress*

NATIONAL COMMITTEE FOR THE UNITED STATES

ARTHUR W ALLEN, Boston, Massachusetts, *Chairman*
ALFRED BLALOCK, Baltimore, Maryland, *Vice-Chairman*
W BARCLAY PARSONS, New York, New York, *Secretary*
FREDERIC W BANCROFT, New York, New York, *Treasurer*
HARRY H KERR, Washington, District of Columbia, *Recorder*

ADVISORY COMMITTEE FOR THE UNITED STATES

RUDOLPH MATAS, New Orleans, Louisiana, *Honorary Chairman*
CHARLES G MIXTER, Boston, Massachusetts
ALLEN O WHIPPLE, New York, New York
HARVEY B STONE, Baltimore, Maryland
I S RAVDIN, Philadelphia, Pennsylvania
DALLAS B PHEMISTER, Chicago, Illinois
EVARTS A GRAHAM, St. Louis, Missouri
FREDERICK A COLLIER, Ann Arbor, Michigan
ALFRED W ADSON, Rochester, Minnesota
HOWARD C NAFFZIGER, San Francisco, California
IRVIN ABELL, Louisville, Kentucky
DANIEL C ELKIN, Atlanta, Georgia
ALTON OCHSNER, New Orleans, Louisiana

Inquiries should be directed to

COLLECTIVE REVIEW

COLONIC AND PROCTOLOGIC DISEASES

ROBERT TURELL, B S, M D, and ALBERT S LYONS, M D, F A C S, New York, New York

THIS review covers some of the pertinent papers which appeared in the literature between January, 1946 and August, 1948. It also includes a number of reports published in 1945 which were omitted from our last review (273). In this article consideration is confined to the presentation of the more recent knowledge, both the advances and the retreats, in the study of function and diseases of the anorectocolonic tract. We have also summarized some of the recent information which has a bearing on colonic and anorectal surgery, such as chemotherapy and hemostasis.

BASIC INVESTIGATIONS

Lannon and Weller observed on dissection that the parasympathetic nerve fibers of the distal colon arise from the second and third sacral nerves and are distributed directly to the descending colon, although they send communicating branches to the hypogastric plexus. In general, the parasympathetic distribution does not follow the arterial blood supply. Because of the sacral origin, a parasympathetic function is attributed to these basic independent fibers. The parasympathetic nerve supply of the lower colon consists of from three to six fibers on each side of the bowel. The authors supported their thesis with clinical, physiologic, and roentgenologic evidence, as well as with the work of Lawrentjew who showed that each parasympathetic fiber on entering the wall of the intestine branches out and unites with a great number

of ganglion cells in the colonic enteric plexuses. Because of this multiplication phenomenon only a few parasympathetic fibers are necessary to transmit impulses up and down the entire lower colon.

The practical implications are as follows:

1. The pelvic parasympathetic nerves are interrupted in resection of the rectum and lower pelvic colon.

2. Resections of the colon proximal to the midpoint of the descending colon (point of entry of the highest sympathetic colonic fibers) will cause a break in continuity of the colonic plexuses at the point of resection. It remains to be demonstrated whether this interruption of sacral sympathetic pathways will result in functional disturbance of clinical importance of that portion of the colon between the point of resection and the distal point of vagal supply which is in the proximal transverse colon (see Arendt's discussion).

3. Periaarterial stripping of the inferior mesenteric artery advocated for the treatment of megacolon will cause no parasympathetic dysfunction since the authors have shown that the colonic parasympathetic nerve supply does not follow the arteries.

4. Presacral neurectomy would not result in vital damage to the parasympathetic function of the rectum or lower colon because the parasympathetic nerves do not have a close association with the hypogastric plexuses.

Kratzer and Dockerty confirmed the presence of preformed anal ducts in monkeys, human embryos, and adult human beings. The anal ducts course outward and downward from the

This review originated from the Surgical Services of Dr. Leon Ginzburg, Beth Israel Hospital, and Dr. John H. Garlock, Mount Sinai Hospital, New York, New York.

emerging at the anus to become continuous with the stratum corneum of the skin was described by Duran-Jorda. Because of the rapid autodigestion this layer can be visualized microscopically only on freshly removed surgical specimens. These anatomic studies are discussed in relationship to the histopathology of ulcerative colitis.

The employment of orally administered slightly soluble sulfonamides as adjuvants to colonic surgery is almost universal. Collier, who in the past had not utilized these drugs, stated in his most recent paper on colonic cancer that the advent of sulfonamide drugs made possible the safe return to the one-stage colonic resection. This view coincides with the expressed opinion of Behrend and others. However, it should be remembered that for unexplained reasons even large doses of these drugs may be ineffective in the occasional patient (219).

Poth (210) has recently stated that when the slightly soluble sulfonamides are properly administered they will modify the bacterial flora of the colonic contents, allow a satisfactory preoperative mechanical preparation of the large intestine, favor early healing at the line of the suture or anastomosis and reduce the incidence of postoperative peritonitis and wound infection. He (209) stated that on the third postoperative day the control animals showed edema, extensive polymorphonuclear infiltration, but no evidence of revascularization or fibroplasia, while in the treated animal, healing and orderly fibroplasia, revascularization, slight edema, and moderate polymorphonuclear infiltration were discernible. Advanced healing of the intestine following open suture was noted by the fifth postoperative day in the treated experimental animals, while little evidence of healing was discernible in the control animals. Bell in a comparative study showed that the incidence of infection and mortality rate were lower in patients in whom a slightly soluble sulfonamide drug was employed preoperatively than in those in whom the drug was not used. Also, by lowering the incidence of infection the recovery period was shortened. Pemberton (204) revealed that at the Mayo Clinic the fatality rate before 1939 varied between 15 and 20 per cent. A slight decrease occurred in 1939, the year in which the sulfonamide drugs were first casually or intermittently used, and then in 1940 there was a precipitous decrease to around 5 per cent where the rate has since remained. With this decline in mortality rate there was an appreciable increase in the surgical resectability rates of colorectal lesions. Furthermore, before the "sulfa" era about 6 per cent of the patients died

of postoperative peritonitis, whereas with the employment of the sulfonamide compounds the mortality rate from peritonitis has been reduced to about 1.7 per cent. Similarly, the mortality from postoperative bronchopneumonia was reduced from 22 to about 0.6 per cent. A 50 per cent reduction of fatal pulmonary embolism during the period of sulfonamide chemotherapy has also been observed. Pemberton believes that the changes in colonic surgery since the introduction of chemotherapy have been as spectacular and revolutionary as those produced by iodine therapy in the surgery of exophthalmic goiter.

The healing time of anorectal wounds was not influenced by these drugs (248).

Because of the occasional tendency toward bleeding during the administration of the slightly soluble sulfonamide drugs, as observed by Sanders and Halperin, and Bell, it is advisable to administer vitamin K preoperatively and postoperatively. The bleeding may be caused by a disturbance in the prothrombin time as a result of the interference with synthesis of vitamin K in the intestinal tract. These remarks are true also of the oral administration of streptomycin (219).

A fatal reaction to sulfathalidine has been reported (251) in a woman aged 28 years who developed acute myocarditis; the pathologist described the myocarditis as "probably due to sulfathalidine" after the administration of a total dose of 32 gm. This solitary case serves as a reminder that this drug, in common with other sulfonamides, may be dangerous.

Sodium phthalylsulfacetimide, the newest of the slightly soluble sulfonamide drugs, is now being subjected to clinical investigation (238).

Boyd and Dingwall (38) showed that the oral administration of a suspension of microcrystalline sulfadiazine, a soluble sulfonamide, has an advantage over tablets in that higher concentrations of the drug in the blood were attained more quickly. These authors (39) also showed that lactates accelerated the absorption of sulfadiazine microcrystals from the gastrointestinal tract and gave higher initial concentrations of the drug in the whole blood and in blood plasma. Lactates also accelerated the output of total and free sulfadiazine in the urine and increased the urinary pH. Lactates are preferred to other salts. No signs of renal damage or other untoward clinical reactions were observed.

Lehr investigated the toxicity, absorption, and secretion of combinations of sulfadiazine-sulfathiazole, sulfadiazine-sulfamerazine, and sulfadiazine-sulfathiazole-sulfamerazine in albino rats. These combinations of partial dosages were de-

prior to streptomycin, its toxicity in experimental animals, however, is greater than that of penicillin or streptomycin

Duca and Scudi observed that methenamine mandelate is not much different from sulfathiazole and streptomycin in its activity against organisms isolated from infections of the urinary tract. Resistance to methenamine mandelate, in contrast to resistance to streptomycin and sulfathiazole, is either absent or insignificant. Furthermore, micro-organisms that become resistant to sulfathiazole or streptomycin are susceptible to methenamine mandelate. These facts appear to be of importance in the treatment of urinary tract infection following proctectomy.

With regard to new hemostatic agents, Correll and Wise showed that thrombin and penicillin are rapidly destroyed by oxidized cellulose, but that their potency was not affected by solutions in which absorbable gelatin sponges were suspended. The destruction or inactivation of thrombin by oxidized cellulose was also observed by Olwin and Wahl. This destructive effect is believed to be produced by the extreme acid character of oxidized cellulose which may cause local annoying irritation when applied to anal wounds (274). Streptomycin was found to be stable and ascorbic acid showed little deterioration in the presence of either of these hemostatic agents (62). Rosser (227) discussed the use of oxidized cellulose and the absorbable gelatin sponge as dressings in anorectal wounds. He believes that both of these hemostatic agents satisfy the criteria for desirable postoperative anal dressings. They should be applied as small single dressings to individual wounds and should not be used as an occluding pack. Pruitt seems to favor oxidized cellulose, while Kerr, and Turell (274) prefer the gelatin sponge.

Laufman and Method studied the effects of absorbable hemostatic agents on colonic anastomosis of dogs unprotected by sulfonamides or antibiotics. In most dogs they observed that when the hemostatic substances were applied to anastomoses of the descending colon there resulted a deleterious local reaction which caused disruption of the anastomosis and eventuated in fatal peritonitis in most of the experimental animals. In the few dogs in which the anastomosis was unaffected there was evidence of a greater peritoneal reaction than in the control animals. It is suggested that when absorbable hemostatic agents are used in open intestinal surgical procedures they should be eliminated before the peritoneum is closed or other means of hemostasis should be utilized.

It remains to be determined whether sulfonamides or antibiotics will overcome the deleterious effects of the hemostatic agents and render these substances useful in colonic anastomoses.

NEOPLASMS—BENIGN

An adenoma is a glandular structure showing proliferation of the colonic epithelium without invasion of the wall of the bowel. This lesion is generally regarded as a benign tumor. Helwig (119) reported a comprehensive investigation of adenomas based on a study of 1,460 consecutive autopsies in which the entire colon was available for examination. The problem of evolution of adenomas and their relation to carcinoma received special attention. He believes that adenomas are not the result of a reaction consequent to an inflammatory process although many may contain inflammatory cells. Also, lymphoid nodules are not prerequisites to the development of adenomas. The incidence of polyps increases with age. The small adenomas preserve a regular outline, while the larger ones may be lobulated or villous. Most adenomas are pedunculated. Close scrutiny will disclose short stalks that are missed on routine examination. Microscopic studies reveal structural variations among different adenomas as well as in single adenomas.

The incidence of adenomas has been reported as high as 69 per cent (13). Exclusive of the first year of life, approximately 3 per cent of children have adenomas (118).

Helwig is of the opinion that the colonic carcinomas usually develop in adenomas. In this opinion he is joined by many authorities (13, 57, 120). In agreement with Swinton and Warren (*J Am. M. Ass.*, 1939, 113, 1927), Helwig considers anaplasia, irregularity of architecture, and invasion as the microscopic criteria for determination of the fact whether a cancer arises from an adenoma. Atwater and Bagen believe that a benign adenoma is but "one stage in the pathogenesis of a carcinoma." In advanced lesions the progression of a malignant process may destroy the original adenomatous architecture beyond histologic recognition (119, 269).

On the other hand, Colvert and Brown believe that rectal adenomas are either malignant in the beginning or tend to become malignant very early; they found no evidence that malignancy tends to develop in benign adenomas with the passage of time.

It is generally conceded that when a single adenoma is found, the entire colon should be examined by all means at our disposal in a search for additional polyps. This includes sigmoidos-

be extirpated effectively by electrothermy or local excision. Adenomas showing invasion into the rectal wall should be regarded and treated as frank carcinomas.

There still is a need for unanimity of nomenclature or classification of colonic polyps.

Lymphomas are always benign, often polypoid in character, resembling adenomas, and usually appear as solitary nodules. They are free from associated generalized lymphoid disease, the main associated lesions are hemorrhoids and prolapse. Li studied 26 benign lymphomas of the rectum seen during the period from 1920 to 1946 and reviewed 23 additional cases reported in the literature. Her histopathologic description is as follows: "It is a noncapsulated yet well-circumscribed and often lobulated nodular growth which is composed exclusively of lymphoid tissue. This in turn is framed or supported by reticular tissue. The submucosal nodule often extends through the muscularis mucosae and involves the mucosa. Invasion of the underlying muscular coat has never been observed. The nodule is made of units of lymph follicles which contain all the cellular elements normally found in the lymphoid follicles of the intestine. Mitotic figures, regardless of their number, remain well within the limit of the germinal center. The number of mitoses varies among different follicles from the same case as well as from one case to another. A diffuse infiltration of different forms of wandering cells in varying intensity is many times encountered. The overlying mucosa suffers from compression of the underlying nodular growth, becomes, therefore, thin and straightened, and is thus exposed to mechanical injury." Lymphomas are differentiated from adenomas and lymphosarcomas by histologic and cytologic means. Lymphosarcomas are composed of small lymphoblasts in the case of the lymphocytic cell lymphosarcoma or of large cells in the case of reticulum cell lymphosarcoma. The differentiation is difficult when the tumor contains giant follicles. There is no evidence to support the view that lymphosarcomas can develop from lymphomas. It has not yet been determined whether lymphomas are true neoplasms or simple localized hyperplasias.

It is worth emphasizing that in addition to enumerating the histologic features of lymphomas, Li considers lymphomas as benign because recurrences were not observed in 33 of 49 patients who had been followed up for various periods of time.

Ehrlich and Hunter (85) reported 53 instances of benign lymphoid polyps of the rectum which

they considered as belonging to the lymphoma group. These tumors responded well to local excision, no later recurrences or transformations into malignant states have been observed.

Carcinoids are most commonly confused with adenocarcinomas. None of Ehrlich's 10 carcinoids in the rectum was treated by radical measures, however, Jackman (134) regards carcinoids as a low grade type of malignant lesion which may be invasive locally and in some instances may show extensive metastasis. The first case of multiple carcinoids of the rectum was recently reported (225).

To date only 32 carcinoid tumors of the rectum have been reported. Of these, 4 have been associated with distant (liver, kidney, thyroid, and distant lymph nodes) metastases (Pearson, C, and Fitzgerald, P. J. *Ann Surg*, 1948, 128: 128).

Lazarus and Marks reviewed 37 benign tumors of vascular origin arising within the intestinal tract and reported 1 personal case. Eight vascular tumors occurred in the colon alone. The pathologic diagnoses were as follows: 6 nevi, 11 angiomas, 11 cavernous angiomas, 5 capillary angiomas. Associated skin nevi were present in 3 instances. The tumors occurred singly or multiply. Profuse intestinal bleeding was the outstanding symptom. Single tumors that were amenable to resection yielded the most satisfactory therapeutic results, the prognosis for multiple tumors was poor.

Intestinal endometriosis can best be diagnosed microscopically (See also gynecologic aspects). Endometriosis may coexist with cancer, and sometimes may undergo malignant degeneration. It has been estimated (261) that from 2 to 4 per cent of all women during active menstrual life have some degree of rectosigmoidal invasion or infiltration of endometrial tissue. Castration without intestinal resection will cure intestinal endometriosis. McGuff believes that discreet endometrioma of the bowel causing intestinal obstruction in young women in whom the pelvic organs are essentially normal calls for a radical bowel operation with a conservative genital procedure.

Tenner reported an experience with 12 intestinal lipomas. The colon is a frequent site of lipoma, which is a differentiated benign neoplasm. Ulceration of the mucous membrane covering the lipomas was observed in 11 instances. The ulceration is ascribed to pressure injury as in intussusception, to trauma as in partial obstruction, or to infarction as from pressure on the blood vessels from the growth and development of the tumor. A preoperative

be extirpated effectively by electrothermy or local excision. Adenomas showing invasion into the rectal wall should be regarded and treated as frank carcinomas.

There still is a need for unanimity of nomenclature or classification of colonic polyps.

Lymphomas are always benign, often polypoid in character, resembling adenomas, and usually appear as solitary nodules. The tumors occurred singly or multiply. Profuse intestinal bleeding was the outstanding symptom. Single tumors that were amenable to resection yielded the most satisfactory therapeutic results, the prognosis for multiple tumors was poor.

Intestinal endometriosis can best be diagnosed microscopically. (See also gynecologic aspects). Endometriosis may coexist with cancer, and sometimes may undergo malignant degeneration. It has been estimated (261) that from 2 to 4 per cent of all women during active menstrual life have some degree of rectosigmoidal invasion or infiltration of endometrial tissue. Castration without intestinal resection will cure intestinal endometriosis. McGuff believes that discreet endometrioma of the bowel causing intestinal obstruction in young women in whom the pelvic organs are essentially normal calls for a radical bowel operation with a conservative genital procedure.

Tenner reported an experience with 12 intestinal lipomas. The colon is a frequent site of lipoma, which is a differentiated benign neoplasm. Ulceration of the mucous membrane covering the lipomas was observed in 11 instances. The ulceration is ascribed to pressure injury as in intussusception, to trauma as in partial obstruction, or to infarction as from pressure on the blood vessels from the growth and development of the tumor. A preoperative

diagnosis of a malignant lesion is frequently made largely because of the obstructive nature of the disease and the age of the patient, the average age of this group of patients was 53 years. Intestinal obstruction may be produced directly by the lipoma or indirectly by intussusception due to the tumor. Lipomas may originate submucously, intramuscularly, intermuscularly, or subserously. The treatment is surgical, local excision through a colotomy is the procedure of choice. Occasionally, resection of the segment of bowel containing the lipoma is performed. Occasionally lipomas are expelled spontaneously.

Jackman (134) stated that although most submucosal nodules are benign, some of the asymptomatic submucosal ones of the rectum discovered on routine proctoscopic examination may be malignant or may possess malignant propensities. These isolated nodules are covered by normal mucous membrane and may vary in size from a few millimeters to 3 or 4 cm in diameter. These lesions may be confused with mucosal or anal polyps, or extrarectal masses. At the Mayo Clinic the exact nature of such nodules in 87 consecutive patients was determined by excision and microscopic examination. Among the benign lesions there were 49 chemical tumors which resulted from the therapeutic submucous injection of sclerosing solution (a history of antecedent injectional therapy is helpful in the differential diagnosis), 3 fibromas with adherent overlying mucosa, 3 lipomas with a freely movable overlying mucosa, 2 leiomyomas with a freely movable mucosa, 24 inflammatory lesions (8 phlebotomias, 1 fecalith, 2 enlarged lymph nodes, 3 mucous cysts, 2 enlarged lymph follicles, 4 inflammatory reactions about cholesterol crystals, and 4 other examples of an inflammatory process). The other lesions consisted of 2 lymphosarcomas and 4 carcinoids.

NEOPLASMS—MALIGNANT

The importance of an expert knowledge of the blood supply of the colon in the presence of malignant tumors was stressed by Hinton and Localo. They presented color illustrations of the blood supply of the colon and indicated which vessels are to be preserved at the various levels of resection of segments of the colon. Thus, in resection of the right colon, when the terminal ileum, cecum, ascending colon, and hepatic flexure are removed, the right colic artery is ligated but the middle colic artery is preserved. The colon is sectioned at a 45 degree angle in order to insure an adequate blood supply at the antemesenteric border. In resection of the

transverse colon the left colic artery is preserved. In some instances, the middle colic artery may also be preserved. Wangensteen and Toon (280) divide the middle colic artery when the marginal vessels are well developed. In resection of the splenic flexure, branches of the middle and left colic arteries are ligated, but the main arteries are preserved. In resection of the rectosigmoid, the superior hemorrhoidal artery is ligated, and the upper sigmoidal, middle, and inferior hemorrhoidal arteries are preserved.

Bacon and Smith (22) described and correlated the pattern of the arterial blood supply of the sigmoid and upper rectum with their technique of abdominoperineal proctosigmoidectomy.

Wangensteen and Toon (280) pertinently pointed out that the term rectosigmoid is a rather arbitrary and not strictly anatomic designation. The present arbitrary upper limit of the rectum is at the level of the third vertebra and the segment of colon between this upper rectum and the distal sigmoid is termed rectosigmoid. However, this anatomic designation is not accepted by all surgeons.

Some describe the rectosigmoid as the point at which the sigmoid loses its mesentery. The bowel below this level is considered to be the rectum.

The most common type of malignancy encountered in the colon is adenocarcinoma which may occur in a nodular, scirrhous, colloid, or papillary form (27, 57). The neoplasm may be single or multiple (about 5 per cent are multiple). Rewell reported 2 rectal cancers in sisters, one had multiple colonic polyposis and the other had multiple telangiectasis. Mider recorded 21 patients with multiple carcinomas of the colon. Ehrlich and Hunter (85) stated that the carcinomas of the colon and rectum make up 80 per cent of all neoplasms of the intestinal tract.

A study of the site of the growth of 1,457 carcinomas of the colon by Boehme and Hanson showed that about 75 per cent of these lesions were located in the sigmoid, rectosigmoid, and rectum. It also showed that about 70 per cent of the colonic cancers can be palpated digitally or detected sigmoidoscopically. This is in agreement with Jackman, Neibling, and Waugh (136) who found that of 817 patients studied 54.3 per cent had malignant lesions palpable digitally, and in an additional 16.2 per cent the lesions could be detected sigmoidoscopically. It is also of interest to note that of the remaining 29.5 per cent of patients, 28.4 per cent had carcinomas that were detectable on roentgenography and only 1.1 per cent had malignancies which were discovered at abdominal surgical exploration.

The spread of carcinoma occurs by direct local extension and through the blood or the lymphatic streams. It is emphasized that the colonic lymphatic vessels usually follow the arteries. Miles, as early as 1908, stated that cancer of the rectum may spread upward, laterally, and downward. Subsequently it was shown that the downward spread is uncommon and occurs only when the lymphatics above the tumor are blocked by metastasis. It was also believed that the intramural spread of cancer cells occurs rarely below the lower margin of the tumor. Gilchrist and David (100) in a recent article again showed that the lymphatic spread is primarily embolic, and that further spread is checked in the lymph node until it is completely overwhelmed by carcinoma. Then further embolic spread may continue through the collateral channels, spread from node to node is uncommon. They also reported retrograde metastases in nodes 1 to 5 cm below the lower border of the neoplasm in 7 of 153 cases of malignant lesion situated below the promontory of the sacrum. Connell and Rottino studied the intestinal segments below the border of the malignancy by making hundreds of serial sections of the bowel wall in each of the 9 specimens studied, clearance of the lymph nodes alone was not relied upon. They found malignant tumor cells in lymph channels of one specimen as far downward as 7 cm from the lower border of the neoplasm. Intramural tumor cells were found in 4 additional specimens. Bacon and Rowe (19) reported that 146 specimens of bowel removed at operation were sectioned serially at 2, 4, and 6 cm below the neoplasm with the finding of invasion in only 1 instance at a 6 cm level. Venous invasion was also observed in 12.9 per cent.

Also, it has now become increasingly appreciated that carcinomas situated in the region supplied by the inferior and middle hemorrhoidal blood vessels, particularly neoplasms in the ampulla, spread laterally along the vessels, the levator ani muscles, and sometimes caudally through the ischiorectal fossa. This lateral lymphatic spread of rectal carcinoma demands radical surgical procedures and imposes definite restrictions on operations that do not remove the perirectal structures with the associated lymphatics (see later discussion).

The content of potassium and calcium in colonic carcinomas and papillomas was studied by Dunham, Nichols, and Brunschwig. They observed that the carcinomatous mucous membrane contains less calcium and more potassium than the adjacent normal mucosa. In papillomas

the potassium content was similarly increased, but the degree of reduction of calcium was less marked than in the carcinomas.

Herly, by introducing methyl-cholanthrene into the abdominal cavity of young male mice, produced ascites in 50 days and sarcomas in those mice which survived for 90 days. This ascitic fluid, when introduced intra-abdominally into other mice of the same strain, produced ascites and malignant tumors. When the ascitic fluid of the second series of mice was introduced intra-abdominally into a third series, ascites and sarcomas again were produced. The undetermined active tumor-producing agent could be destroyed by ether and by exposure to a temperature of 90° C.

Rabinovitch, Grayzel, Swyer, and Pines reported a study of 5 cases of sarcoma of the colon and 9 of the small intestine. Their comparative studies showed that the relative proportion of sarcoma to carcinoma of the small intestine is approximately 1 to 5.5, of the large intestine 1 to 275, and of the rectum 1 to 577. They emphasized that, contrary to the general belief, carcinoma of the small intestine occurs more frequently than sarcoma.

Sarcomas arise from specific constituents of the intestinal wall. The lymphosarcomas resemble lymphoid tissue normally present in the intestinal wall. The reticulum-cell sarcomas resemble the large pale-staining cells forming the reticulum of the lymph follicles. Thus, this tumor is also believed to arise from lymphoid tissue. The leiomyosarcomas resemble the smooth musculature of the intestine. The neurofibrosarcomas consist of nerve fibers and connective tissue and originate from the nerve elements of the intestinal wall. Apparently complete resection of these lesions offers the best prognosis.

The occurrence of lymphosarcoma in a pedunculated rectal polyp was reported by Harris and Feigen. This polyp was successfully removed with a high frequency diathermy snare followed by desiccation of the base. No recurrence was observed after a lapse of 5 years.

Goldman and Marbury described a spindle-cell sarcoma of the rectum which was treated by perineal resection of the rectum and the establishment of a permanent abdominal artificial anus (Lockhart-Mummery procedure). They stated that the incidence of true primary rectal sarcoma is rare, one of 200 rectal malignancies is a sarcoma. The treatment of choice is early radical resection because local excision, irradiation, and radium are followed by frequent recurrence.

Many years ago Curtice Rosser (*Am J Surg* 1931, 11 328) called attention to the occasional development of malignant tumors in anal fistulas. To the growing record of case reports, Skir (247) added 3 cases of mucinous carcinoma which were associated with anal fistulas. Skir believes that the preformed anal glands may be the origin of the glandular elements of these neoplasms. Dukes reported 2 cases of colloid cancer of the anorectal region extending deeply along the track of an anal fistula without the formation of a tumor in the rectum or anal canal. Pearse added another case of cancer of the rectal colloid type associated with a fistula-in-ano without rectal involvement. Harvey called attention to the relation of anal fistulas and other causes of chronic irritation about the anus to the occurrence of anal epitheliomas.

As noted in the discussion of adenomas, many investigators believe that carcinomas frequently originate or develop in adenomas. Mider, in a study of 726 cases of colonic cancer, showed that 17 per cent of the patients with single cancers and 38 per cent of the patients with multiple cancers had polyps elsewhere in the colon but more usually near the site of the cancer.

Thomas, Kline, and Seed stated that an appreciable loss of weight occurs early in the course of rectal carcinoma and that a history of alternating diarrhea and constipation, a supposed frequent accompaniment of cancer of the rectum, is found only in 5 per cent of patients, although a change in bowel habit, either diarrhea or constipation, is observed often. Collier and Berry found that all of their patients who had alternating diarrhea and constipation had the carcinoma in the sigmoid colon. Jones, Robinson and Meads (140) pointed out that there is no standard set of symptoms for rectal carcinoma and that the patient's history alone is unreliable.

Most writers agree that well over 70 per cent of the patients with rectal and colonic carcinoma have symptoms for 9 months or longer before a correct diagnosis is made. Jones *et al* (140) believe that the duration of symptoms depends on three factors: (1) the patient's failure to consult a physician before the condition is in a far advanced stage, (2) disregard of medical advice, and (3) improper diagnosis of the lesion in its early stages.

Practically all writers agree that a high incidence of hemorrhoids is observed in association with carcinoma of the terminal portion of the large intestine. Hemorrhoids are often observed 6 months before the correct diagnosis of cancer is made, and about 75 per cent of the patients

undergo hemorrhoidectomy (57, 140). To avoid this serious error, no hemorrhoidectomy is performed at the University of Michigan Hospital until a sigmoidoscopy and roentgenography (double contrast barium enema) are performed. A summary of the diagnostic errors of carcinoma of the colon has been reported by Jackman *et al* (136).

Jones *et al* (140) claimed to be able to make a correct diagnosis on the gross appearance of the lesion and therefore believed that biopsies are unnecessary. Furthermore, they stated that biopsy may be misleading since "biopsies of superficial tissue do not reveal the disease when a biopsy of tissue from deep in the tumor would." In this connection it should be pointed out that a properly performed biopsy aims at securing fragments of tissue from the deep as well as the superficial components of a tumor. Also, it has generally been considered good practice to obtain histologic confirmation of a clinical diagnosis before a patient is subjected to a major surgical procedure of a radical scope, especially one necessitating an artificial anus. Only thus can an error of mistaking an inflammatory or benign lesion for a malignancy be avoided (185). Wakefield stated that a malignant lesion should not be recorded in the history sheet without histologic substantiation.

Preoperative rehabilitation in the unobstructed patient may be accomplished in from 5 to 10 days and this program may be begun at the patient's home (113, 174, 186).

The value of antibiotics and sulfonamides is discussed separately elsewhere in the text. Suffice it here to report that Jones (140) is among the very few surgeons who does not employ these agents preoperatively.

Vitamin B complex is needed because of its influence upon carbohydrate metabolism. Vitamin C is essential to the effective healing of the wounds (186). These and other available vitamins may be given orally and parenterally in maximum dosages. It should be remembered that in the presence of hypoproteinemia, vitamins are poorly absorbed and utilized.

A desirable diet is one of low residue containing 100 or more grams of protein and 500 or more grams of carbohydrate (186). In the event that the patient cannot handle such large quantities of protein, in the form of natural foods, protein digests may be administered (56, 125, 185, 198). These products are highly digestible and provide but little bulk. When the oral or orogastric methods of feeding are contraindicated resort may be made to jejunal feeding.

When none of these routes can be utilized, intravenous injections are used as the sole source of dietary intake (185, 255)

Meyer and Kozoll (185, 186) prefer whole blood to other proteins for transfusion because of (1) its more rapid effect upon the raising of the circulatory protein levels, (2) its provision of both plasma and hemoglobin as protein metabolites, and (3) its inclusion of many immunologic factors that are vital to the resistance of infection. They advocate the administration of a minimum of 2000 c.c. of blood before and during an intestinal resection. Blood transfusions are combined with the administration of amino acids. This program also corrects anemias that might be masked by dehydration, increases the oxygen carrying capacity of the blood, and tends to prevent the occurrence of shock during or after operation.

Enemas consisting of 6 gm. of succinylsulfathiazole and 10 gm. of sodium carbonate per 1,000 c.c. of warm water are given by Meyer and Kozoll (185) the day preceding surgery and are repeated until the rectum is absolutely clear. Allen *et al.* (3) believe that vigorous cathartics should not be used as perforation and peritonitis may occasionally result from their use. It may also be added that preoperative purges may contribute to postoperative distention.

It is generally agreed that the presence of colonic obstruction calls for decompression by cecostomy or transverse colostomy prior to the institution of rehabilitating measures. Allen *et al.* (3) condemn exteriorization procedures as well as exploration of the abdominal viscera in the presence of complete acute obstruction because manipulation of the bowel may lead to fatal peritonitis.

Millet has recently suggested a method of cleansing the colon through a tube colostomy opening (Gibson's technique) by means of a Miller-Abbott tube which is carried gradually by peristalsis to the point of obstruction. Solutions introduced through one lumen are removed by suction through the other lumen and the bowel is thus thoroughly cleansed in about 5 days. Millet's procedure is claimed to enhance the value of tube cecostomy and to be preferable to transverse colostomy because secondary closure is usually avoided. This procedure has also been found useful for the postoperative decompression of the anastomosis.

The present day tendency in many clinics in the treatment of colonic carcinoma is definitely toward the return to the one-stage resection with primary anastomosis, (3, 57, 125, 163, 180, 182,

185, 186, 187, 219, 278, 282). There still is a lack of unanimity of opinion concerning the open versus the closed method of anastomosis, and the desirability of a proximal vent.

The proponents of primary resection believe that a more radical technique of resection is possible than in the exteriorization resection procedures because more of the lymphnode-bearing area and of bowel adjacent to the tumor can be excised, also, that primary resection eliminates the necessity of several operations and, thus, prolonged hospitalization is avoided, and that the complications of exteriorization, such as retraction of either or both of the loops, prolapse, infection or disruption of a wound, and incisional hernia are eliminated (57, 186).

The open type of intestinal anastomosis is vigorously championed by Meyer (186), McNealy (180), and their associates. Recently, Allen *et al.* (3) and Fansler have abandoned the aseptic method of anastomosis in favor of the open technique, this seems to be a current trend in many clinics. The most important arguments in favor of the open procedure are the established safety as based on the actual performance of large numbers of open anastomoses, the precision and accuracy with which the sutures may be placed, and the opportunity that is afforded for the direct inspection of the interior of the ends of the bowel that are to be anastomosed. Thus, the presence of polyps that may have been missed or obscured by the neoplasm, as well as the character of the bowel adjacent to the neoplasm, can be established.

Stanton (252) described a device for the elimination of unequal diameters of the 2 colonic segments to be anastomosed with a view to simplifying the procedure of end-to-end anastomosis.

The construction of a proximal vent in unobstructive lesions is considered unnecessary by many surgeons (57, 180, 187, 282).

Interrupted sutures of fine stainless alloy steel wire or silk for the serosal layers are favored by Meyer, Sheridan, and Kozoll (187). They believe that wire sutures are less likely to form a sinus through which infection might drain. Hoxworth (129, 130) stressed the fact that serosal sutures should catch the submucosa but must not penetrate the mucous membrane, and that these sutures should be tied tight enough to hold the serosal surfaces in apposition without strangulation of the involved tissue in order to avoid tissue necrosis, thus re-emphasizing Halsted's original teachings which constitute the beginning of modern gastrointestinal surgery (*Am J M Sc*, 1887, 94:436).

Of the 250 described methods of intestinal anastomosis, 45 are said to be aseptic or nearly aseptic. Hinton and Localio advocated an aseptic closed method of intestinal anastomosis utilizing the Furniss clamp. Collier and Berry reported a postoperative period of hospitalization of 17.2 days for the closed type of anastomosis as against 27.4 postoperative hospital days for the open method. This, however, is at variance with Meyer *et al* (185, 186) who reported a postoperative hospital sojourn of an average of only 13 days. Parenthetically, by way of contrast, Collier and Berry reported an average period of 55.9 postoperative days following obstructive resection procedures.

The mortality following primary anastomosis is around 5 per cent (57, 187, 219, 282).

The case for the obstructive resection procedure for colonic cancer is again presented by Jones (138). He believes that this procedure is as adequate for cure of cancer as is resection with immediate re-establishment of intestinal continuity. Following obstructive resection performed by him, Jones has never seen a single case of local recurrence in the abdominal wall, which he interprets to mean a thorough elimination of the involved mesenteric glands. Jones believes that because he does not have to worry about the blood supply he can do a more radical procedure with the Rankin type of resection than he could with an end-to-end anastomosis. This is in agreement with the experience of Garlock and Klein (95). Allen *et al* (3) have minimized the fear of compromising the blood supply in any colonic resection by first removing the neoplasm and then determining by visualization whether the blood supply of the ends of the bowel to be anastomosed is adequate.

Garlock and Klein list four situations in which obstructive resection is to be preferred to primary anastomosis: (1) great disproportion in the size of the bowel proximal and distal to the lesion, accompanying chronic obstruction, (2) pericolic abscess or infection, (3) excessively fat mesentery obscuring the vascular pattern, and (4) poor general condition incident to advanced age.

Other surgeons are supplanting obstructive resection techniques with resection and primary anastomosis (57, 186, 187, 219). The factors that made this possible are the employment of sulfonamide drugs and antibiotics, the copious use of blood and blood substitutes, the correction of malnutrition, and the improved techniques of anastomosis. Both types of procedures have their place, although more and more cases are being found suitable for primary anastomosis.

A great controversy is now raging concerning the merits and demerits of operations that aim to conserve sphincter control, particularly of the so-called "anterior resection," in cases of rectal carcinoma. This procedure implies primary anastomosis of peritoneum-covered colon to the nonperitonealized rectum (31, 174) with division and ligation of the superior hemorrhoidal artery, and excludes anastomoses between peritonealized segments of the bowel. The anterior resection operation is predicated on the assumption that the downward lymphatic spread of rectal carcinoma occurs rarely or only for a few centimeters below the growth (102). Some investigators have challenged this assumption (61, 100). The fact that important lateral spread occurs from ampullary carcinoma, especially when situated at the level of the levator ani muscles, has influenced some surgeons to avoid the performance of anterior resection. Because abdominoperineal resection is the most radical cancer operation, it is preferred to the sphincter-saving operations by many surgeons (2, 47, 100, 138, 150, 152, 217, 254). This orthodox operation not only removes involved lymph nodes and perirectal structures, such as the levator ani muscles, but also excises the venous channels which may be left behind in the anastomotic procedures. The findings by Gilchrist and David (100) of 23.2 per cent of local recurrence following the Miles procedure for cancer of the extraperitoneal part of the rectum indicates that the more radical the removal of the rectum the greater the chance of cure. Rankin agrees with Gilchrist and David "that the sphincter-saving operations are little more than local excisions for all cancers situated below the peritoneum." Stewart (254) believes that "some rectal cancers can be cured by resection and end-to-end anastomosis," but that "a far higher percentage will be cured by the combined abdominoperineal excision which includes lymph nodes and blood vessels in the zone of spread of the disease." Allen (2), Mad dock, and others justify the sphincter-saving procedure if the patient has hepatic metastases at the time of operation.

Wangensteen (280), who has been among the earliest proponents of anterior resection, in his latest and very frank and instructive paper, has summarized the present status of this operation.

1. Lesions situated at 8 cm or less from the anus should not be treated by this procedure because of the high incidence of local recurrence. He has given up the anastomotic procedure for these low-lying malignancies in favor of the abdominoperineal resection of the rectum. He also pointed out that local recurrence has not been

invasion of the surrounding tissues only 15 per cent were well 5 years, and 11 per cent were well 10 or more years after operation. Colcock also noted that 60 per cent of the patients with rectal carcinoma without local invasion or nodal metastasis were well 5 years and 51.6 per cent were well 10 years after operation. Only 30.2 per cent of patients with rectal carcinoma associated with nodal metastasis or local invasion of the surrounding structures were well 5 years, and 23.2 per cent were well 10 or more years following resection of their malignant lesions. It was further noted that although some patients with cancer of the colon and rectum survive 5 years, they will ultimately die of their disease, but more than 50 per cent of the survivals in whom nodal metastasis and local invasion of the surrounding tissues are absent may expect a permanent "cure" of their malignant disease if they are subjected to radical surgical resection.

Gilchrist and David (100) observed the survival of 114 of 200 (57 per cent) patients with cancer of the colon for from 5 to 10 years. In their experience, 78.5 per cent of the patients without nodal metastasis had a survival rate of from 5 to 10 years, this figure could be increased to 90.9 per cent if the patients who were lost to the follow-up and those who died postoperatively of other causes after leaving the hospital were taken into account. Of 125 patients with nodal involvement, 56 (44.8 per cent) lived 5 years, this survival varied with the location of the colonic cancer. Thirty-seven per cent of the patients with a lesion in the middle and left colon or the extraperitoneal portion of the rectum survived 5 years, a 61.5 per cent survival was noted in patients with lesions in the right colon, and a 51.4 per cent survival, in patients with a lesion in the sigmoid and intraperitoneal portion of the rectum. Local recurrence developed in 23.2 per cent and liver recurrences developed in 15.9 per cent in neoplasms of the extraperitoneal portion of the rectum, in the remainder of the bowel local recurrences were either not easily demonstrated or developed less frequently. The rate of hepatic metastasis varies from 10 to 15 per cent and usually results when cancerous emboli travel up the liver via the hemorrhoidal blood vessels.

That a routine autopsy examination may fail to demonstrate small retroperitoneal nodal metastasis is indicated by Gilchrist's findings of the presence of metastases in the nodes of the peritoneal tissues in 4 of 11 patients who had had previous routine postmortem examinations. In 3 of these patients complete removal of all in-

volved nodes would have been possible if the field of resection had been 1.5 cm wider.

Gilchrist and David reported that 2 of 3 of their pregnant patients with carcinoma of the colon lived more than 5 years. This experience is in contrast to the gloomy prognosis usually given. Bacon and Rowe (18) reported their recent experience with 4 patients with carcinoma of the rectum occurring during pregnancy. An uneventful recovery followed the performance of an abdominoperineal proctosigmoidectomy with preservation of the sphincter muscles.

The majority of anal carcinomas are squamous-celled epitheliomas, while a small number consist of basal-celled carcinomas and epidermoid cancers (see also section on anal fistulas). Cannon treats such lesions in other parts of the body by desiccation which is carried widely beyond the border of the lesions, the charred material is removed with curette or scalpel, 1,800 roentgens of irradiation are given in 3 divided doses. In 1 case of basal carcinoma, Gross successfully employed wide local excision of the lesion, including adjacent and subjacent tissues. Meland believes that since this type of tumor in other locations of the body is successfully treated by irradiation, this form of therapy should be applied to the anal lesion as well, particularly since irradiation causes no immediate mortality. The period of recovery without recurrence in the successful cases lasts well beyond 5 years. The unsuccessful cases behave like the uncontrolled adenocarcinoma. The minority of the patients develop metastases in the inguinal glands, whereas the majority show metastatic spread to the retroperitoneal glands, the liver, and even the brain.

Sweet studied the comparative merits of surgery and irradiation. He stated that although irradiation was applied to the small and locally favorable (noninvading) lesions and surgery was applied to the large and advanced (invasive) tumors, the results both as to cure and good palliation were superior in the surgically treated group. Radical surgery produced cures in 12 of 48 cases (25 per cent), whereas irradiation produced a cure in 1 of 19 cases (5.2 per cent). The degree of relief from local symptoms is greater and the duration of the relief is longer in the surgically treated cases as evidenced by the fact that 41.6 per cent of the patients experienced complete relief from local discomfort as compared with 15.8 per cent of the patients (exclusive of the recurrent cases) who obtained similar palliation after irradiation. Sweet naturally concluded that irradiation is inferior to surgical

Glass and Garlock described 13 instances of radical resection of the colon and rectum together with the involved adjacent viscera with a mortality of only 15 per cent. The uterus, vagina, the urinary bladder, the stomach, the ureter, loops of ileum, and the abdominal wall were the structures involved. The survival period was surprisingly long, and the patients were saved the complications incident to the spread of the neoplasm. Sugarbaker presented his experience with 42 cases in which additional organs were removed in order to accomplish the eradication of the neoplasm of the rectum and colon. Dixon and Benson (74) perform extensive resections of the urinary bladder when it is involved in the sigmoid area. Brunschwig and Morton reported on the feasibility of resecting colonic neoplasms and secondarily involved livers and spleens.

Dunphy (81) believes that patients with recurrent colonic and rectal cancer associated with involvement of neighboring but nonvital structures, but in the absence of distant metastases or generalized peritoneal seeding, should be reoperated upon regardless of the extent of previous resection, the size of the lesion, or its apparent fixation. Gratifyingly long periods of arrest after block excision of recurrent lesions may follow reoperation for locally recurrent and apparently hopeless cancer.

Binkley and Deddish (32) outlined in detail the complications of abdominoperineal resection for carcinoma of the rectum and reported a significant reduction of these complications during the past 5 years. Infection of the urinary tract and retention of urine were the most troublesome and consistent of the postoperative difficulties. Bacon and McCrea (17) believe that the preoperative administration of slightly soluble sulfonamide drugs (not employed by Binkley or Jones) exerts a bacteriostatic effect on organisms found in the urinary tract.

Marshall *et al* have stated that bladder dysfunction occurs more commonly after perineal excision of the rectum, and that they have been unable to demonstrate neurogenic dysfunction as the underlying cause. On the other hand, Bacon and McCrea (17) believe that injury to the nerve supply (trauma or severance of the sympathetic and parasympathetic nerve fibers—see Lannon and Weller's paper) is responsible for the vesical dysfunction. Marshall believes that in the absence of bladder neck obstruction the dysuria is caused by sagging of the bladder, vesical neck, and prostate into the hollow of the pelvis following the removal of the support af-

forded by the terminal bowel. For this group of patients he advises elevation and fixation of the bladder and urethra. Vesical neck obstruction responds to the surgical removal of obstructing tissue.

Fallis described a technique of transverse colostomy in which no sutures are used to attach the bowel to any of the layers of the abdominal wall. Closure of the colostomy is effected by the intraperitoneal end-to-end open method of anastomosis. Wangenstein (279) described a loop colostomy which, he believes, secures complete fecal diversion. Two glass rods are drawn through the mesentery and maintained in position until the wound is healed. The colon is opened by a slit in the axis of the bowel and the proximal orifice is unroofed by cutting away a small portion of the antemesenteric intestinal wall. Rank and Smith described a colostomy which utilized a buried inverted skin tube and a mechanical plug.

Lahey (153) believes that the perineum is a poor place for colostomy and prefers the abdominal artificial anus. Rankin stated that the majority of experienced surgeons agree with Pfeiffer that "the uncontrollable perineal colostomy is infinitely inferior to the abdominal anus in all respects except sentimental nonsense." The well functioning colostomies have the mucosal level well above the skin level. A colostomy should be inspected daily for several days after operation to make sure of the blood supply. Should an accident to the blood supply occur within 4 days after operation the wound can be opened and a longer segment of bowel pulled out. After 4 days the unnourished segment of bowel becomes necrotic with the attendant danger of rupture and contamination.

The management and complications of permanent colostomy are well described by Jones and Kehm (139). In 76 of 100 patients studied good fecal control was obtained by regular irrigations. Gabriel opposes, but Gordon Watson and Milligan (189) advocate daily irrigations if a natural rhythm does not develop after a short trial. It may be added that a newly designed Ray Patten irrigator is one of the best now available.

Colcock (55) observed that 64.3 per cent of 81 patients with carcinoma of the colon without nodal metastasis or local invasion of the surrounding tissues survived 5 years without recurrence of the neoplasm, and that 57.1 per cent were well 10 or more years after the successful radical extirpation of the malignant neoplasm. Of the patients with lymph node metastasis 0

fective obliteration of the dead space with fine cotton sutures, and (5) complete closure of the mucosal defect Kenney reported that in 11 of 12 patients the wound healed by primary union without complications or recurrence during a period of observation ranging from 2 to 6 months

The experience of one of us (R T) with primary closure of anal fistulas was not as successful as Kenney's and this procedure was therefore abandoned

The occurrence of malignancy in an anal fistula is discussed in the chapter on malignancy

Jackman and Buie (135) studied 600 patients with anal fistula and found an incidence of 11.5 per cent of tuberculosis somewhere in the body This observation, they believed, justifies a suspicion of tuberculosis in every patient with an anal fistula About 7 to 8 per cent of their material was tuberculous but their data do not permit an opinion as to whether the tubercle bacillus is a primary or secondary invader of anal fistula A properly performed but negative guinea pig test excludes tuberculosis A positive test and a negative histologic examination suggests that the tested tissue was contaminated

Ditmore still advocates digital dilatation under anesthesia for the cure of the painful lesion of fissure (ulcer), but adds that "the fissure should be relatively small, the base should be smooth and there should be a minimum of scar or any other elastic tissue" In our experience this type of acute anal lesion usually responds to the topical application of a bland ointment and to hot hip baths alone Occasionally the oil-soluble "anesthetic" solutions are employed If these measures fail, we employ surgical therapy Because of the smooth convalescence and good results which follow operative treatment the latter is preferable to dilatations which are traumatic in character and result in tears of the muscle fibers and extravasation of blood into the sphincter muscle which may become secondarily infected

Turell (274) described a rational surgical procedure for the eradication of chronic anal fissure The operation includes wide excision of the ulcer-bearing area, the extirpation of the involved anal crypt or crypts with the sentinel pile and polyps, and the performance of a posterior sphincterotomy A subcutaneous portion of the external anal sphincter muscle, which in many instances of chronic anal fissure is fibrosed and indurated, is incised at right angles to its fibers If considerable fibrosis exists, a small part of this muscle is excised in order to prevent early reapposition and to insure ample drainage

Kornblith claimed that sulfonamide drugs administered orally and Frei antigen given intravenously to patients with venereal disease in the prestricture stage produce beneficial clinical effects in the acute and subacute states Improvement in the anatomic changes as observed sigmoidoscopically were slow until many months of treatment had elapsed Healing was delayed because of the accompanying acute pathologic process in the pelvic lymph nodes

Costello and D'Avanzo advised periodic proctoscopic examinations in all cases of venereal lymphogranuloma in order that the development of anorectal involvement may be discovered promptly They also advised the performance of an intracutaneous test with Frei antigen in all cases with prolonged and obscure rectal complaints

Neither sulfonamide drugs nor Frei antigen exert a therapeutic effect on fibrosis which is the end stage of the local inflammatory process and a formidable complication of venereal lymphogranuloma

Estrogen, parahydroxyphenyl-ethyl-hexane, administered orally in doses of 30 mgm daily was claimed by Seley, Vernick, and Goldman (237) to have had a beneficial effect upon rectal strictures These findings, however, were not confirmed by Schreiber

Penicillin has proved valueless

In general, it may be stated that systemic therapy for fibrous stricture is of value only in eliminating the toxic effects of secondary infection because the blood supply through and to the dense scar tissue is so diminished that adequate therapeutic concentration of any drug is rarely possible

Dilatation, digital or instrumental, is contraindicated in the tubular forms of stricture but may be useful in the diaphragmatic or ring types The last type of stricture may be resected advantageously with a Turell electric loop resector (*Surgery*, 1942, 12 729)

Wright *et al* believe that only surgical treatment is of value once an extensive fibrous stricture has developed Colostomy helps by lessening secondary infection and by overcoming the effects of chronic bowel obstruction Warthen's technique of obliterating the pouch of Douglas offers the possibility of lessening the chance of anterograde and retrograde herniation of the colostomies This operation, however, cannot prevent constriction of the colostomy stoma, which often occurs in cases of venereal lymphogranuloma Strictures low in the rectum were treated successfully by Wright *et al* by means

excision either as a method of cure or as a palliative procedure for relief of the local symptoms. The surgical methods which he employed were (1) local excision in 2 cases, (2) combined abdominoperineal resection in 28 cases, (3) colostomy with posterior resection in 20 cases, and (4) colostomy for obstruction in 3 cases. Bernstein strongly endorsed the radical form of surgical therapy as described by Miles (*Surg Gyn Obst*, 1931, 52:350).

Muller stated that in the gastrointestinal tract the anal region is the most common site of melanomas. These tumors constitute from 2 to 3 per cent of all malignant neoplasms. This author believes that melanoblasts are derived from the ectoderm which is the probable origin of melanomas. The tumors occurring near the anus are the most heavily pigmented. Melanomas are solid and tend to infiltrate the rectal wall. Ulcerations are superficial without necrosis or deep crater formation. Metastases occur frequently and extensively. About 87 per cent spread to the liver and 50 per cent to the lungs and pleura. Significantly, the retrorectal lymph glands are involved much more frequently than the inguinal glands. Radical surgery is mandatory because of (1) the infiltrative nature of the neoplasm and the necessity for the extirpation of the regional lymph nodes, even if they show no clinical signs of involvement, and (2) the marked radioresistance of this tumor. The mortality rate is about 78 per cent with the possibility of a 5 year cure in about 13 per cent.

Pack *et al* used the term "melanoma" to designate the malignant tumor, and the term "pigmented nevus" or "neuronevus" to indicate the benign variety. Their reported experience with 13 anorectal melanomas is probably the largest single collection on record. None of their patients survived 5 years. Pack *et al* advised wide and deep excision of the primary lesion, which consists of the removal of from 6 to 10 cm of adjacent skin with a still wider area of the deep structures en masse. The involved regional lymph nodes are removed preferably "in continuity" at the time of the initial operation or about a fortnight later. Apparently, these authors, unlike Muller, do not remove the retrorectal lymph nodes. Radiation therapy is considered completely ineffective.

INFECTIONS

Courtney (64, 65) presented original anatomic studies based on the dissection of 8 human cadavers and elucidated the complex pathways of infection of the deep perirectal and posterior

levator spaces. The reader is referred to his original papers for study of the important illustrations. It is apparent from these studies that the primary source of infection, in the vast majority of instances, resides within the anorectum (anal duct). In other cases infection may originate in the anal glands, secondarily extending into the anal crypts via the preformed anal ducts. The location of the primary crypt opening can usually be accomplished with relative ease either by observing the discharge of purulent material or by gently probing the crypt with a ball-pointed flexible metal probe from within the anus. If these maneuvers are unsuccessful the abscess cavity is incised, unroofed, and gently explored digitally. An attempt is then made to pass a probe without force from the abscess cavity into the suspected anal crypt. Under certain circumstances it is safe to perform a simultaneous fistulectomy. However, large or deep abscesses with fistulas are best treated by staged operations. In general, McGivney (1,6), Wenzel (286), and Whitney (289) are in agreement with the foregoing.

The embryologic considerations of pyogenic anal fistulas were ably discussed by Young (295). He restated the concept that vestigial anal glands and ducts (in common with the prostatic glands and paraurethral glands in women) originate from the cloacal membrane. The anal crypt and the associated intramuscular sinuses of Herrmann are foci and precursors of anal fistulas. Young believes that anal cryptitis precedes perianal and rectal abscess with resulting fistula, and that it is "detonated" by a precipitating cause such as trauma or diarrhea. He proposed a surgical treatment consisting of (1) severance of the fibers of the sphincter muscle over the fistulous tract at right angles to their course, (2) wide "paring back" of the rapidly regenerating anal epithelium away from the severed ends of the sphincter muscle in order to allow sufficient time for the sphincter to re-establish its continuity completely, and (3) removal of a sector of anal epithelium as well as of any hemorrhoidal elements opposite the fistula wound. Young believes that a redundant contralateral surface of the anal canal may stimulate the ill advised gauze pack by wedging the sphincter wound during healing. By utilizing this surgical procedure the seton will not often be necessary.

A primary closure technique of anal fistulas was presented by Kenney. This operative procedure consists of (1) careful anatomic dissection of the tract, (2) infiltration of the wound with penicillin solution, (3) good hemostasis, (4) ef

fective obliteration of the dead space with fine cotton sutures, and (5) complete closure of the mucosal defect Kenney reported that in 11 of 12 patients the wound healed by primary union without complications or recurrence during a period of observation ranging from 2 to 6 months

The experience of one of us (R T) with primary closure of anal fistulas was not as successful as Kenney's and this procedure was therefore abandoned

In general, it may be stated that systemic therapy for fibrous stricture is of value only in eliminating the toxic effects of secondary infection because the blood supply through and to the dense scar tissue is so diminished that adequate therapeutic concentration of any drug is rarely possible

Dilatation, digital or instrumental, is contraindicated in the tubular forms of stricture but may be useful in the diaphragmatic or ring types The last type of stricture may be resected advantageously with a Turell electric loop resector (*Surgery*, 1942, 12 729)

Wright *et al* believe that only surgical treatment is of value once an extensive fibrous stricture has developed Colostomy helps by lessening secondary infection and by overcoming the effects of chronic bowel obstruction Warthen's technique of obliterating the pouch of Douglas offers the possibility of lessening the chance of anterograde and retrograde herniation of the colostomies This operation, however, cannot prevent constriction of the colostomy stoma, which often occurs in cases of venereal lymphogranuloma Strictures low in the rectum were treated successfully by Wright *et al* by means

of endoanal excision with preservation of the sphincter. A preliminary colostomy was usually employed. When the entire rectum was involved or the disease was high in the rectum, abdominoperineal extirpation of the rectum was employed. In the cases with involvement of the descending colon, a permanent transverse colostomy was advocated.

Superimposed carcinoma occurred frequently enough to be of clinical importance.

Kaiser and King reported their experience with 38 deliveries in the presence of pelvic venereal lymphogranuloma with rectal stricture. Three cesarean sections were performed because of widespread scarring of the soft tissue in the pelvis. The mortality among the reported 162 cases in the literature was 6 per cent. Force in delivery played a large role in the reported fatalities. Version and extraction is absolutely contraindicated. Death is usually due to rupture of the rectum or uterus. Hence, these patients should be observed diligently for signs of peritoneal irritation or shock. Colostomies present no special obstetric problems.

Steer believes that the gravity of the possible complications warrants advice against pregnancy in a patient with active disease or a rectal stricture, and furthermore suggests consideration of termination of pregnancy if it has occurred. In the presence of rectal stricture, cesarean section is the method of choice for delivery.

Berkowitz mentioned the rare location of granuloma inguinale in the anal region. This lesion is caused by a gram-negative, nonmotile bacillus identifiable by smear or biopsy in the state of encapsulation, known as a Donovan body. Streptomycin appears to be effective (24, 28, 143), but must be continued for a prolonged period of time (41 days in 1 case).

Bacon and Gass (15) discussed all phases of syphilis of the anorectum. It should be noted that the addition of antibiotic therapy has exerted a very beneficial effect in this disease.

Diverticulosis and diverticulitis. The problem of diverticulosis and diverticulitis of the entire gastrointestinal tract was discussed by Nash and Palmer and Gerwig. This lesion is most commonly found in the sigmoid. Anderson ascribes the preponderance of diverticula in the left colon to the solidity of the fecal stream, the smaller diameter of the bowel and the occasional presence of fecaliths in the diverticula which obstruct drainage. Defecation occurs when the fecal mass fills the rectum and creates a pressure of between 40 and 50 mm of mercury. It is the sigmoid that bears the brunt of the effects of this pressure.

The familial aspects of diverticulosis are discussed by Schlotthauer who described a family of 7 brothers who had this condition although their 2 sisters did not. The occurrence of this lesion in 100 per cent of the male members and 78 per cent of the entire family suggests the consideration of heredity as an additional etiologic factor to the known causes such as physical forces, degenerative changes in the muscular layer incident to age and trauma, diet, and congenital defect in the intestinal wall.

Cohen and Matthews reported a heretofore undescribed form of diverticulum which began as a herniation of the lumen into the wall of the colon and burrowed its way along the wall. The authors apply the term "dissecting or intramural diverticulitis" to this lesion. The details of a report of a 60 year old patient are presented in which the sequence of events were sacculization, intramural diverticulum, isoperistaltic propagation, diverticulitis, dissecting diverticulitis, tension pneumodiverticulum, and ileus.

Morton stated that diverticulitis with spasm should be treated conservatively, treatment in general calls for good judgment and patience on the part of the physician and the patient. Pemberton *et al* (205) stated that surgical treatment is determined by the presence or absence of obstruction, the extent of peridiverticulitis and inflammation of the mesocolon, and the accessibility of the affected section of the colon. The safest procedure is the formation of a colonic stoma orad to the lesion with exteriorizing resection performed at the later date. Primary resection and anastomosis without preliminary colostomy may occasionally be performed in the absence of obstruction when the inflammation is subacute in character and only a small segment of the colon is involved. It should, however, be added that a concomitant colostomy is a good safeguard. The diverticular segment of the colon should be excised prior to closure of the colostomy. Cave and Alsop (49) prefer cecostomy to colostomy in acute obstruction, while Pemberton (205) prefers a colostomy. Abscess formation may be prevented by early diversion of the fecal stream. Localized abscess is best treated by incision and drainage.

The treatment of acute perforation usually varies between (1) drainage of the area of rupture with or without closure of the opening, and (2) exteriorization and resection of the colon. Proximal colostomy or cecostomy (98) is often combined with these procedures.

The surgical treatment of fistulas secondary to diverticulitis requires individualization. The be-

method is one that employs preliminary diversion of the fecal stream, preferably a transverse colostomy, and resection of the fistula-bearing bowel after the inflammatory process has completely subsided. Sabeti has stated that sigmoidovesical fistulas are best treated by a three-stage operative procedure, namely, (1) the construction of a diverting proximal colostomy, (2) separation of the diseased bowel from the urinary bladder with repair of the vesical opening and resection of the diverticular segment of the bowel, and (3) closure of the colostomy. The bladder should be drained during the second stage either by the suprapubic route or via an indwelling urethral catheter.

In elective surgery the preoperative preparation and the postoperative care should be the same as in cases with colonic neoplasms.

The coexistence of carcinoma with diverticulosis was discussed by Oren who reported 2 personal instances in which a correct diagnosis was made preoperatively. Pemberton *et al* (205) pointed out that the 2 conditions are grossly similar and at times resection of the diverticular mass is essential for the establishment of a correct diagnosis. There is still considerable uncertainty as to what extent diverticulitis is incidental or etiologically directly contributory to the rare occurrence of carcinoma in diverticula.

Dixon and Benson (75) outlined the principles which are employed in the management of external fecal fistulas, based on the experience with 65 cases. There were 2 hospital deaths (3 per cent). Early operation is avoided both because many fistulas close spontaneously and because acute inflammation must subside before operation can be successful. Before institution of surgery several conditions should be met if possible: (1) the causes of the fistula should be determined, (2) the segment of intestine from which the fistula arises should be ascertained, (3) the patency of the bowel distal to the lesion should be known, (4) an adequate trial of conservative management should have been made, (5) the general condition of the patient should be improved, and (6) all evidence of acute inflammation should have subsided.

In this series, the causes were diverticulitis, regional enteritis, intestinal cancer, chronic ulcerative colitis, tuberculous enteritis, actinomycosis, pelvic inflammatory disease, extraintestinal tuberculous abscess, osteomyelitis, foreign bodies, and contraction of scar tissue with encroachment on the lumen of the bowel.

Conservative surgical treatment may consist of simple curettage of the tract (occasionally

successful) or short circuiting procedures. These sidetracking operations are very valuable as (1) a preliminary procedure to aid in the resolution of inflammation, (2) a first step in improving the nutritional state of a patient in poor general condition, (3) a palliative procedure in cases of large, perforating, inoperable cancers, and (4) a form of definitive treatment which can result in complete subsidence of the fistula. Sidetracking procedures consist in ileocolostomy for fistulas arising in the right colon and ileum, ileostomy for those with ulcerative colitis, and proximal colostomy for lesions in the left colon. The colostomy is best placed at a distance from the diseased site. Usually a preliminary transverse colostomy is necessary before any resecting procedure for perforating diverticulitis of the sigmoid is done.

In planning a resection (either following a sidetracking operation or as a one stage procedure) the type of incision is important. Dixon and Benson favor an incision surrounding the fistulous tract rather than a remote approach through a clean field, as the latter leaves the fistulous tract intact and requires reperitonealization of the raw surface in the abdominal wall from the inside. In the majority of cases, the peritoneum should be opened and the intestine mobilized. Extrapentoneal procedures have a limited usefulness in the occasional accidentally produced fistula with mucous membrane of the bowel and skin in close continuity. The extent of resection depends on the amount of diseased tissue, all of which must be removed. This may include bowel resection or resection of only a small rim of normal intestinal wall. An adequate intestinal lumen must be provided for.

The most difficult types of external fistulas to treat are those associated with (1) pelvic inflammatory disease, (2) severe diverticulitis, (3) bone infection, and (4) abdominal actinomycosis. (Also see section on gynecologic injuries elsewhere in the text.)

MECHANICAL AND DEGENERATIVE CONDITIONS

Clardy believes that the anorectum has received less consideration by general surgeons than any other part of the body. He condemns instrumental or digital avulsion of the anal sphincter muscles, clamping of large masses of tissue, burning or cauterization with hot irons, unnecessary suturing, and the removal of great areas of mucosa and skin. He described a simple technique of hemorrhoidectomy. The hemorrhoidal mass is grasped at each end with an Allis forceps. The mucosa and skin are incised on both sides and are pulled toward the base. The

Excision of the intervening and adjacent scar and reapproximation of the freshened muscle ends with a Bunnell-like tendon suture of No. 0 chromic catgut are advocated by Turell, Gordon, and Davis (276). In addition, a few interrupted sutures are introduced into the tissues under the muscle to obliterate possible dead space and to relieve tension on the sphincter muscle stitch. The subcutaneous tissues are approximated with interrupted sutures and the skin is left unsutured. Sulfonamide and antibiotic therapy is employed before and after operation.

Zager reported the histories of 3 workers in whom anorectal symptoms appeared after heavy lifting or pulling. These individuals were granted compensation since the causes for awards under the Workmen's Compensation Act include aggravation of the symptoms as well as direct cause of the symptoms. Since massive rectal prolapse is considered a form of sliding hernia, it is reasonable to parallel its compensatory features to those of inguinal hernia.

There is a need for comprehensive study of the relation of physical strain and increased intra-abdominal pressure to the development of hemorrhoids and prolapse. Many medical officers serving with the Armed Forces during World War II believed that (1) there was a definite increase in the incidence of hemorrhoids in the military personnel as compared to civilians of the same age, and (2) that this increase was due to accelerated physical activity and muscular strain.

Simon *et al.* (245) noted backache and an ineffectual urge to defecate without abdominal pain, tenderness, and distention as a common symptom of volvulus of the colon.

Griffin *et al.* distinguished 2 types of sigmoidal volvulus, (1) the acute and (2) the subacute varieties. The acute cases run a fulminating course as gangrene develops early, while the subacute forms usually occur in the older age group and run a moderate course. Because of the tendency toward recurrence following detorsion, exteriorization followed by resection as a second stage is advocated. Recently, Bruusgaard has stated that primary resection with anastomosis after detorsion is an effective elective method of treatment and may be carried out after proper intestinal preparation. Gilchrist (99) believes that obstructive resection is the surgical procedure of choice.

A successful nonsurgical method of treatment was described by Bruusgaard who believes that in most cases of sigmoidal volvulus there is torsion of the sigmoid with obstruction of the lumen, but without strangulation or serious cir-

culatory disturbances. He employed proctoscopy and intubation with a rectal tube 60 cm. long and from 6 to 10 mm. in diameter, in 123 patients suffering from acute volvulus without evidence of serious circulatory disturbances in the sigmoid. A sigmoidoscope was introduced to the site of the torsion with the aid of careful insufflation. The site of torsion was easily recognized by the characteristic screwlike or spiral folds and a lubricated soft rubber rectal tube was introduced without force past the site of obstruction. Following the passage of the tube prompt evacuation of flatus and soft feces occurred with instant relief. The tube was left indwelling for 2 or 3 days and was held in place by a suture to the perianal skin. In 9 instances, attempts at intubation by proctoscopy were unsuccessful, probably because of the firmly fixed twist of the sigmoidal loops. It should be pointed out that this method of therapy has no effect on the tendency toward recurrence of this lesion, and is therefore not a definitive treatment. Other authors (293) consider conservative decompression as an emergency measure that will make possible subsequent elective resection of the redundant sigmoid colon.

Spontaneous untwisting of the sigmoid colon may occur when torsion is less than 360 degrees, in torsion of 360 degrees the twisted loop is usually held fast between the anterior and the posterior abdominal wall. Detorsion may occasionally follow a simple enema or a diagnostic barium enema (181).

Andresen reported a series of 46 cases of perforations of the rectosigmoid resulting from sigmoidoscopy, which had been gathered by questionnaire. These were compared with 48 cases collected from the literature. About 50 per cent of these 94 cases resulted in death. Spontaneous recovery occurred in 9 cases, in these a walling off of the perforation may have occurred. Conservative treatment is advocated for cases in which the perforation is not recognized within 24 hours or in which the patients are poor risks. In the early cases, closure of the rent of the bowel should be performed as soon as the patient has recovered from shock.

Walker reported 1 instance of rectal perforation after sigmoidoscopy in a patient with amebiasis. The injury was repaired but the postoperative convalescence was stormy. The peritoneal drainage yielded cysts of *Endamoeba histolytica* (*Brit. M. J.*, 1946, 1:434).

Andresen pertinently emphasized that the sigmoidoscope should always be passed under visual guidance, and if sigmoidoscopy is not possible

because of persistent angulations of the bowel, fecal accumulation, bloody or other discharges, the presence of new growths or other objects obstructing the lumen, or the struggles of a nervous, unco-operative patient, the endoscopic examination should be discontinued immediately.

Pratt and Jackman collected 20 reported cases of perforation of the rectum due to the enema tube, and to these they added 2 personal cases. The perforations apparently occur most often either in pregnant women at term or in persons over 50 years of age, and are usually found on the anterior rectal or rectosigmoidal wall. The normal bowel of a conscious individual can be perforated without the use of much force, and the colon of an older person is particularly vulnerable to tears. The best treatment is prompt surgery (identification and repair of the injury) as the mortality rate rises in the first 4 or 5 hours. Location of the rent at the time of operation is facilitated by the insertion of a catheter into the rectum to mark the approximate level of the tear.

Davis reported 3 cases of perforation of a colostomy loop caused by an enema tube used for irrigation. Two patients were operated upon on the day of the injury, while the third patient was explored 3 weeks following the perforation. All survived. Davis believes that an enema tube should not be inserted into the colostomy loop farther than the depth of the abdominal wall. This may be accomplished by the employment of David's method, in which an inverted rubber nipple (similar to the type used on a baby's bottle), with a catheter through its center, is inserted into the colostomy. This provides a water-tight compartment and allows hydrostatic distention of the bowel, which avoids pressure necrosis and perforation incident to direct pressure of the enema tube on the bowel wall.

Shidler reported his experience with perforations of the colon and rectum in Navy personnel, stating that death usually occurs if the time interval between bowel injury and definitive surgery is more than 18 hours. Colcock (54) described experiences with 120 soldiers who sustained perforating colonic and rectal wounds. He ascribed the decreased morbidity and mortality during World War II to adequate transfusions of blood, antibiotics, and the skill of the operating surgeon. Welch reviewed at length reports in the literature dealing with abdominal war wounds (Also consult our last review, 273).

Blaisdell discussed the causes and treatment of traumatic injuries of the rectum in civilians. McLanahan and Johnson described the seventh

case in the literature of spontaneous rupture of the lower colon with evisceration of the small intestine through the anal orifice.

Falk and Hochman reported on intestinal injuries in 42 women which occurred during gynecologic laparotomies. Usually these injuries are recognized at the time of operation and are repaired successfully. In some cases trauma to the intestine results in necrosis and in fecal fistula or fatal peritonitis. Fistulas of the colon or terminal ileum usually heal spontaneously. The authors advise that sufficient time be allowed for the fistula to close spontaneously before surgical repair is attempted.

Spackman called attention to the late effects upon the intestinal tract of irradiation therapy for uterine cancer. Incomplete or complete intestinal obstruction may be produced by vascular changes and cicatricial contraction fibrosis. Usually the sigmoid is involved, but any segment of the small intestine lying low in the pelvis or in the area of active irradiation may be affected.

Leiter and Lyons reported an unusual case of persistent postoperative paralytic ileus that responded to cecostomy after all other available conservative therapeutic measures had failed. The successful result may have been due to improvement in the circulation of the colon resulting from the elimination of retained fluid and gas, which broke the cycle of colonic distention, stasis, and impaired circulation.

Remington *et al* reported 2 cases of stenosis of the colon secondary to chronic pancreatitis. This cause of colonic stenosis is rare, therefore, all colonic strictures should be suspected as being of malignant origin until pathologically they are proved otherwise.

SYNDROMES

The role of allergy in pruritus is apparently little understood, but it is frequently incriminated. The importance of the allergic cause of anal pruritus was discussed by Rugeley, and Whitney (287). Regarding food sensitization, Sulzberger pertinently pointed out that a sharp differentiation should be made between anal itching caused by a contact type of sensitization produced by a food and a pruritus due to an atopic or urticarial type of sensitization to food. The former type of sensitization occurs rather infrequently, whereas the latter type, although frequent, is not generally recognized.

Much has been written about the antihistamine drugs. Ratner stated that neither benadryl nor pyribenzamine are antihistamine chemically or pharmacologically. Feinberg and Bernstein be-

lieve that pyribenzamine applied topically, preferably in a water-soluble base, affords symptomatic relief in the treatment of pruritus ani and in cases of atopic dermatitis. However, Sulzberger *et al* failed to confirm their results in the treatment of atopic dermatitis, but noted alleviation of anogenital pruritus in some cases. In our experience, this form of local therapy is effective in a small but definite number of cases of regional pruritus that is recalcitrant to antecedent nonradical methods of therapy. We have, however, also observed the infrequent occurrence of acquired local sensitivity to these drugs with an aggravation of pruritus.

Hoelzel in an experiment performed on himself noted that following the ingestion of cotton fiber and fruit juice he developed anal leakage of fluid and pronounced pruritus ani. Without determining the chemical nature of this fluid he reasoned that a tryptic corrosive (enzymatic) action on the anoperianal skin caused the anal itch. Friedman *et al* carried this work a step further. They made chemical determinations of the anal discharge in 56 individuals and found that the drainage of the patient with moist pruritus contained enzymatic properties similar to trypsin which was probably responsible for the pruritus. The local application of a paste made with aluminum hydroxide gel produced prompt and sustained relief in about 95 per cent of the patients with moist pruritus. This therapeutic agent is believed to inactivate the proteolytic enzyme and other chemical irritants.

With regard to biochemical factors, Bacon and Hardwick (16) postulated that on the basis of recorded studies in the literature, anal pruritus may be caused by disturbances in the gastrointestinal secretions resulting in a change in the bacterial flora and in an elevation of the pH of the rectal mucous membrane. In an attempt to reduce the pH of the rectal mucosa they instituted a regimen consisting of an acid-ash diet and glutamic acid hydrochloride. Gelatin and lactose suppositories were added in an attempt to reduce anal leakage during the night.

The recent introduction of fatty acid drugs (propionates, caprylates, and undecylenates) has improved the therapeutics of fungous infection of the anogenital area (5). These drugs are also bactericidal to a host of nonfungous organisms. Pruritus caused by monilia responds promptly and for a long time to these drugs. In our experience a small number of patients with anal pruritus, suspected but not proved to be due to fungous infection, responded to the fatty acid drugs whereas they had been refractory to other

forms of nonradical therapy, these favorable effects have been sustained. One of the best ointments for the treatment of fungous infection elsewhere in the body contains 5 per cent of undecylenic acid and 20 per cent of zinc undecylenate (258).

Leucoplakia vulvae is included here because of its frequent occurrence in association with anal pruritus. Miller *et al* studied extensively the clinical, histopathologic, and therapeutic aspects of this lesion. Hyams and Bloom have observed little or no free gastric hydrochloric acid in their patients with leucoplakia. Because of the known relationship existing between gastric anacidity and a low plasma level of vitamin A, they administered orally from 250,000 to 500,000 units of vitamin A daily, supplemented by injections of 50,000 units twice weekly. In addition, they gave each patient 1 c.c. of diluted hydrochloric acid 3 times daily. Fourteen of 18 treated patients showed subjective and objective improvement in their condition, the 4 patients who were not benefited suffered from some constitutional disease. It was concluded that this lesion is of metabolic origin and not a neoplasm.

Wilson modified Jelks' procedure which consists of a radial incision through the anoperianal skin to the dentate line without removal of skin. The entire undercut surface is covered with one piece of oxidized cellulose packing. This operative procedure is combined with a partial sphincterotomy and is followed by postoperative digital dilations.

Turell (275) has evaluated the results obtained with tattooing with mercury sulfide. Tattooing with mercury sulfide is advocated for the treatment of intractable anal pruritus which is associated with definite characteristic cutaneous changes in the absence of anorectal colonic disease. It may also be given a trial in cases of persistent pruritus without cutaneous changes, when other radical procedures, such as a subcutaneous injection of ethyl alcohol or the radical excision of anoperianal skin, are being contemplated.

D'Antoni distinguished between the terms "diarrhea" and "dysentery." Both types of stool may show mucus, blood, and pus, but the dysenteric stool also contains cellular debris with little fecal material and its passage is associated with tenesmus, while the diarrheal stool is mainly fecal in composition.

Any continuous or recurrent diarrhea which lasts longer than a month is arbitrarily considered chronic diarrhea. Almost 75 per cent of chronic diarrheas are caused by amebiasis, shigellosis,

and brucellosis, singly or in combination, all three types of intestinal infection may coexist in one patient. The exact diagnosis is established by appropriate laboratory procedures. Amebic cysts or trophozoites are detected on microscopic examination. Shigellosis is diagnosed by repeated cultures of enema specimens, especially of 5 c c specimens collected from the final portion of a second enema. Brucellosis is diagnosed by special tests.

Silverman and Leshe also emphasized that enteric infections caused by *Endamoeba histolytica*, *Bacillus dysenteriae*, and *Bacillus paratyphosus* may exist with a history of minimal or no diarrhea.

The initial treatment of all enteric infections calls for a multiple vitamin preparation of high potency. Shigellosis and brucellosis are treated for a long time with vaccines as in the chronic form these lesions are unaffected by the sulfonamides or antibiotics. Shigellosis is best treated by an autogenous vaccine for over a year as results are not apparent for 6 months. Amebiasis is treated with available amebicides. Resistant amebiasis is treated with a combination of amebicides, penicillin, and sulfonamides.

Levinson and his collaborators (240) found that a vaccine which produced a high degree of immunity in mice failed to protect human beings against experimentally produced bacillary dysentery. These enteric infections were quite severe but were effectively controlled by sulfadiazine, which also rapidly suppressed the carrier state. It appears that the many contradictory reports on the merits of sulfonamide drugs in bacillary dysentery may be due in part to the fact that dysentery is a self-limited disease.

Kiefer pointed out that the present methods of medical therapy for ulcerative colitis are often inadequate except in the milder cases, although severe and complicated cases are occasionally controlled by medical measures.

The successful employment of sodium phthalylsulfacetamide in ulcerative colitis has been reported (Heineken, T. S., and Seneca, H. *Rev Gastroenter*, 1948, 15, 611).

Recently, Ehrlich (86) introduced extract of hog stomach as an addition to the therapeutic armamentarium. He believes that because of intestinal hypermotility there is an increased concentration of the proteolytic enzymes in the colon and rectum which predisposes the colonic mucous membrane to autolysis. To make up for the loss or deficiency of an assumed antiproteolytic intestinal substance, Ehrlich administered from 30 to 60 gm of desiccated extract of hog stomach, in

divided doses, daily before meals to 15 patients for a few weeks to 3 months. Inflammation, ulceration, and spasm disappeared and resulted in an intact mucous membrane. Because of secondary infection, 4 patients were treated with sulfonamide drugs. Another 4 patients suffered a relapse and required repetition of this form of treatment.

Haskell and Friedman reported that the oral administration of a duodenal substance, defatted and desiccated without autolysis, gave beneficial results in patients with nonspecific ulcerative colitis by reducing the frequency of bowel movements, increasing the stool consistency, and causing the disappearance of gross blood in the feces.

The etiologic role of lysozyme (a mucolytic enzyme) in ulcerative colitis is under intensive study in many clinics. At present it is known that (1) lysozyme is present in increased amounts in the stool of patients with ulcerative colitis, and (2) that perfusion of lysozyme through the colon of experimental animals is capable of causing severe ulcerations.

Machella and Miller have treated 12 patients by means of a "medical ileostomy." This consisted in the intubation of the bowel by means of a double-lumened Miller-Abbott tube with constant suction and the oral administration of a protein hydrolysate—dextrimaltose mixture. This therapeutic method aims at providing a temporary period of rest for the diseased colon and at the same time improving the nutrition of the patient.

During the past 10 years, Cave (50) has operated upon 101 patients with intractable ulcerative colitis with 20 immediate or early fatalities. Gain in weight, averaging 45 pounds, was noted in 50 patients. In 2 patients intestinal continuity was re-established by ileosigmoidostomy. Prolapse of the ileum through the stoma is a disabling and serious complication. Acute obstruction due to adhesions or volvulus has also been observed. Following proctectomy the ileostomy assumes, to some degree, the functions of the rectum—the ileal contents become more solid, the lumen enlarges, and the walls thicken.

The technique of the construction of a single-barreled, skin-grafted ileac stoma after the method of Dragstedt was described and utilized successfully in 4 cases by Black and Thomas.

Vagotomy, as the only surgical form of therapy, was introduced by Dennis and Eddy as a means of decreasing intestinal muscular activity without significantly increasing the transit time of the fecal material through the bowel. Pus in the stool disappeared or was diminished. The

general health of the patient improved. It is to be noted, however, in the section on anatomy (elsewhere in the text) that the vagal innervation of the large bowel ends in the transverse colon. It is therefore difficult to understand how a vagotomy can affect the function of the left side of the colon or of the rectum, which are the most common sites of ulcerative colitis. Vagotomy therefore probably produces its effects by decreasing activity of the small intestine and the right colon.

Smith lists polyps, malignant lesions, strictures, perforation, hemorrhage, massive phlebitis, uveitis, arthritis, and cutaneous lesions as complications of ulcerative colitis. Polyps, pseudopolyps, and true adenomas, single or multiple, occur frequently. Polyps are believed to result from the continued attempt of the colon to overcome its destruction. Malignancy seems to occur a long time after the onset of the inflammatory disease. This is in agreement with the experience of Cattell and Boehme (48). These authors emphasize that carcinoma arising on ulcerative colitis is highly malignant and metastasizes early. Strictures of the colon develop even after the performance of ileostomy or colostomy. Perforation and massive hemorrhage are the result of destruction of the intestinal wall by the severe inflammatory process.

Ricketts *et al* reported that 60 of 156 patients with clinical evidence of ulcerative colitis showed a normal colon on roentgenography. This, the authors emphasize, showed that anatomically ulcerative colitis may remain a relatively superficial process in many patients with symptoms of long duration. Variations in the clinical manifestations may take place independently of the roentgenographic pattern. The extent of the roentgenologic involvement cannot be correlated directly with (1) the type of onset, (2) the duration of symptoms, and (3) the clinical severity of ulcerative colitis.

The survival time of the *Endamoeba histolytica* in the feces in dysentery has been studied in Jerusalem by Gurevitch and Delightish. They noted that actively motile trophozoites of *Endamoeba histolytica* survived from 5 to 8 hours in the fecal specimen left at room temperature, but at 37 degrees centigrade the ameba survived only from 2 to 4 hours. These authors agree that the best method for the diagnosis of amebas is the microscopic examination of a fresh fecal specimen, but they believe that the results of the examination are reliable enough if it is performed within 6 to 8 hours. In cases in which immediate examination cannot be made it is advisable to

preserve the feces in the refrigerator. D'Antoni stated that the examination of a single stool following purgation is as effective as the examination of 3 normally passed stools. Hargreaves, and Albright and Gordon deprecated the term "cyst carrier" because every individual who passes cysts must have vegetative amebas living on the tissues of the intestinal wall and completing their development. Cysts from asymptomatic carriers are pathogenic. The development of amebic hepatitis in about one-third of the patients without a history of diarrhea or dysentery suggests that the "carrier" state is a pathologic condition and that it represents an active stage of the disease. Ellenberg (87, 88) believes that the basic pathologic pattern is identical in symptomatic and asymptomatic cases of *Endamoeba histolytica* infection, and that secondary invasion of amebic ulcers by bacterial pathogens is a decisive determinant in the symptomatology of amebic infection.

Proctosigmoidoscopy (and occasional biopsy) is essential in the study of amebiasis. It was pointed out again (Schroder, S, *Proc Am Fed Clin Res* 1948, 4: 47) that some patients with trophozoite in the stool present no intestinal lesions while other patients with suggestive colorectal lesions show no trophozoites in the feces or on smear but respond well to antiamebic therapy. Before instituting treatment, however, we prefer to do a biopsy of the lesion as the trophozoite is frequently found on histologic examination.

The therapeutic armamentarium for amebic infection includes the available amebacides, namely, diodoquin, chiniofon, carbarsone, and vioform. Recently bacitracin, chloroquine (59, 60), and para-aminobenzoic acid (sodium salt) (84) have received therapeutic trials. The sulfonamides (87, 88) and the antibiotics (111) are employed in refractory cases, especially in the presence of secondary infection.

D'Antoni believes that diodoquin is the most effective amebacide, although for some unexplained reason this drug seems less effective than it formerly was. Ellenberg (87) noted good results from carbarsone. In general, the amebicides act on the trophozoites and cysts within the intestinal lumen. However, emetine hydrochloride, given parenterally, acts on the trophozoites within the tissues and is effective against amebas and extraintestinal amebiasis. No other chloroquine (60) has been found to be an effective substitute for emetine in the treatment of extraintestinal amebiasis and particularly in amebic hepatitis. Furthermore, it lacks the toxic centralities, for which reason it is preferable.

emetine Recently, emetine has been employed orally in the treatment of intestinal amebiasis. The enteric coating made possible the oral administration of this drug, which is given in dosages of 0.120 gm daily to adults and of 0.060 gm daily to children for a period of 12 days. These amounts provide a concentration of emetine in the intestinal tract which closely approaches the amebicidal concentration necessary to eradicate the amebas without producing toxic side effects (243).

The toxic action of emetine on the myocardium was studied by Dack and Moloshok. The principal signs of the toxic effects were dyspnea, tachycardia on mild exertion, fatigue, and electrocardiographic changes generally involving the T waves.

The extraintestinal complications of amebic infections consist mainly of suppurations in the liver, the lungs, brain, urogenital organs and skin, especially in the perianal region. Pericarditis is occasionally produced.

In the discussion of the surgical aspects of intestinal amebiasis, Hawe advised conservatism, as surgery may be followed by acute exacerbation of amebic dysentery, local and distant septic complications, intestinal hemorrhage, and delay or failure of normal repair processes. When an exploratory operation is absolutely necessary as in the case of possible appendicitis, the handling of the cecum should be avoided as much as possible. Surgery is indicated for intestinal obstruction or perforation and suppurations. When a rectal ameboma resembles carcinoma, biopsy is necessary as the parasite is usually demonstrable in the specimen.

The treatment of anorectal lesions, such as hemorrhoids, fissures, and fistulas, should be delayed until the underlying disease is eradicated (249). Rarely, a colostomy is of value in the treatment of anorectal fistula.

Rectalgia associated with diarrheal disease may be relieved by a suppository containing ethylaminobenzoate (benzocaine) 3 to 4 times daily (23).

Crohn stated that marriage of patients with ulcerative colitis may be consummated, but that pregnancy should be avoided. It is generally agreed that these patients do well during the period of gestation but often develop severe recurrences a short time after parturition. Cave (50) advised therapeutic abortion after proper consultation for pregnant patients with ileostomy.

Marriage of a man with a permanent ileostomy is possible and many have been successfully married. Prospective marriage of a woman with

a permanent ileostomy is unlikely to be successful, according to Crohn. This also holds true for already married women as an ileostomy is usually repugnant to romance and sex. Fear of infidelity on the part of the husband often leads to anxiety and a fear neurosis in the wife.

However, successful marriages have been consummated by women with ileostomies (A S L).

More and more references to the emotional factors in chronic ulcerative colitis are appearing in the literature. Daniels (69) reiterated the psychiatric factors previously discussed by him and which were discussed in our last review (273). He believes that over 75 per cent of the patients with this lesion have an emotional conflict as a primary causative factor.

Groen attempted through an elaborate biographical anamnesis to establish what had taken place in the emotional life of his patients before the onset of an initial or recurrent attack of ulcerative colitis. This method differs from psychoanalysis in that it does not rely too much on free association or dream-analysis and is also less time-consuming than an analysis. It is the examiner who controls the conversation and sees that the history is related in a chronologic order, the examiner must objectify the findings.

The special peculiarities of character observed and described in detail by Groen are

- 1 A well developed intellect

- 2 Carefulness and neatness, often exaggerated. These patients dislike vulgar or obscene expressions and hate coarse jokes. They are neat in dress and choice of clothes. Some have a flair for fashion. They try to associate with people of a higher social status, thus acquiring a stamp of distinction and respectability. The women have a great sense of cleanliness, are conscientious in the performance of domestic duties, and often continue the meticulous housework long after the disease has undermined their physical strength.

- 3 Extreme sensitiveness, even oversensitiveness. These patients are easily offended and do not get over things of minor importance. They feel ill-treated and fret about it.

- 4 They frequently display hesitation and an unbalanced attitude toward the value of their own personality. While, on the one hand, they have an inferiority complex, on the other hand, they may give the impression that they have a high opinion of their own qualities. Inwardly they are full of criticism of others. The more their confidence is gained, the more they dare to criticize. A strong, but frequently hidden, narcissism is always apparent after prolonged search.

5 Egocentricity is very marked. They may talk about helping other people but actually they are doing nothing outside of their immediate circle. They hardly ever possess political or humanitarian ideas.

6 A passive attitude toward life is frequently exhibited. These patients talk much about what they would like to do but never do anything. They are usually ambitious but to a limited degree.

7 Fear is a dominant feature. In an emergency situation they usually retreat or fail. In any difficult situation they preferably choose the path of least resistance, this attitude may be hidden under a show of manly independence.

8 Lack of aggressive tendencies in behavior is present in most but not in all patients.

9 Love, sympathy and affection, and harmonious surroundings are sought for by these patients. If they do not receive love from others they become utterly helpless and unhappy.

10 They possess an exaggerated, idealistic, frequently naive, and infantile conception of love. They think of love as a sublime adoration, attachment and harmony between husband and wife but consider the bodily sexual contact as something inferior. They cannot establish a normal harmony between their practical erotic and their ideal love life and, consequently, they seldom are capable of normal sexual relationships. Many never marry or marry only after long hesitation. Loss of libido or impotence occurs frequently in male patients. Many of the married female patients have never experienced a normal orgasm as frigidity frequently precedes the onset of colitis. These patients, even the adult ones, frequently practice masturbation which is a marked contradiction to the purity and idealism of their love ideal.

11 Abnormally strong fixation on the mother frequently combined with fear of the father is observed in all male patients. There is no woman who can equal their mother. Some of the male patients have an "instinctive" liking for elderly women. Their attitude toward other men is often reminiscent of the fear or hate they feel toward their father. Some female patients exhibit a strong fixation on the father and an aversion to the mother.

12 These patients repress and worry much more than is apparent, it is difficult to induce them to speak about their inner life. Sometimes they are ashamed of not being able to manage their conflicts themselves.

Individuals with a character structure just described may live undisturbed as long as their

special wishes and desires are satisfied, or as long as they live a sheltered life. However, this sheltered or special life may be easily upset. If a situation arises with which the patient cannot cope and from which he cannot escape, he will conceal it, and in a few days ulcerative colitis will be present.

Treatment consists of 2 parts, namely, an emotional catharsis and simple encouragement of the patient. As a result of this superficial type of treatment the colitis clears up, but the patient remains a neurotic.

Ginsberg and Ivy (*Gastroenterology*, 1946, 7, 67), however, have stated that to date no clearcut evidence has been produced to show that ulcerative colitis is the end result of functional, vascular, or neurotropic derangement, although they concede that emotional factors may play a part in the onset of this condition.

Mucous colitis is very probably merely an expression of or a somatic response to nervous tension, such as anxiety states, submerged fear, guilt, and so forth. Gauss believes that in this disease the life conflict of the patient is mediated through the sympathetic nervous system and is localized in the colon. Psychotherapy combined with somatic treatment is of value. Cures are few, recurrences frequent, and fatalities absent.

It would probably be better to abandon the term "mucous colitis" because the ending "itis" connotes inflammation which is usually absent in this disease.

Lyons demonstrated that sigmoidal carcinoma and diverticulitis are frequently the cause of right-sided symptoms which simulate appendicitis. He suggested the following probable reasons for the contralateral symptomatology: (1) position of the sigmoid on the right of the midline due to mobility or anatomic variation, (2) perforation of the right border of sigmoid or rectosigmoid with spillage of fluid into the right iliac space, (3) extension of perisigmoidal abscess to the right, (4) adherence of right-sided structures to the sigmoidal lesion, (5) marked distention of the cecum, and (6) situs inversus.

Jones (137) advocated thorough surgical intra-abdominal exploration for cases of rectal bleeding of unknown origin. Through a low midline incision he visualizes and palpates all of the small intestine beginning at the ileocecal junction. If the small intestine is normal, the colon is then examined in a similar manner. If this examination gives negative results, the stomach and duodenum are explored through an upper midline incision. This order of exploration was adopted because roentgenography is usually re-

liable for the detection of gastric and colonic lesions, but is of no value in the small intestine except in cases of obstruction

Wilkinson reviewed the literature and presented the surgical anatomy as well as his personal experience with 23 cases of coccygodynia. The pain in this lesion is said to be due to tonic spasm of the pelvic floor or paracoccygeal muscles. Massage of these muscles in the long direction of their fibers, as advocated many years ago by Thiele (*J Am M Ass*, 1937, 109 1271), is often effective. Wilkinson feels that coccygodynia is seldom, if ever, a manifestation of hysteria or psychoneurosis, the apparent neurosis is more likely the result of this painful lesion.

GYNECO-OBSTETRIC ASPECTS

Marbury and Goldman reported 2 cases of suppuration with fistulas following episiotomy, and a third case of anal pain without a definite fistula. While episiotomy constitutes a definite advance in the prophylaxis of rectal injuries due to extensive lacerations of the perineum, it may, however, cause perianal suppuration later and lead to fistulas-in-ano, rectovaginal fistulas, and painful scars. Nicholson believes that whereas the old median episiotomy is subject to the complications described by Marbury and Goldman, the mediolateral episiotomy or perineotomy eliminates anorectal complications since the incision avoids the close neighborhood of the rectum.

Garlock (94) described a plastic procedure which is applicable to the repair of recurrent rectovaginal fistulas associated with extensive scarring. Through a transverse incision in the posterior fourchette a flap of vaginal mucosa is dissected away from the rectum to a level above the fistulous opening. The rectal opening is closed with interrupted sutures of fine chromic catgut with the knots facing the rectum. Each levator ani is mobilized and a flap is cut from the anterior edge of each muscle, to leave a pedicle at the lower end. The right flap is placed across the repaired rectal wall and sewn into place with interrupted sutures of fine silk, the left flap is sutured over the right. Bleeding is controlled and the vaginal mucosa is closed vertically with fine chromic catgut. Complete healing takes place in about a fortnight. This plastic repair eliminates the rigid, poorly vascularized scar tissue and substitutes normal soft muscle. The preoperative regimen is similar to that employed for colonic surgery. Postoperatively, the bowels are kept inactive by a liquid diet and tincture of opium for 9 days. The rectum may then be irrigated. (Also see chapters

dealing with endometriosis, carcinoma during pregnancy, strictures caused by venereal lymphogranuloma, perforation caused by enema tips, intestinal injuries occurring during gynecologic operations, and effects of irradiation)

PEDIATRIC ASPECTS

The anatomic peculiarities of the terminal portion of the colon of the newborn (from birth through the first 3 months), of the infant (from 4 months up to 3 years), and the child (3 years and older) are reviewed by Schapiro. The anal canal of infants and the newborn, as well as the surrounding musculature, is quite elastic and distensible. The infant's rectum is practically vertical in position. The sigmoid is very long and coiled. A well lubricated small finger can be inserted easily in the anal canal of the newborn, while an index finger may be introduced with ease into the anal canal of infants and children. Proctosigmoidoscopy should be performed in an extreme inverted position because of the vertical position of the rectum and the necessity of straightening the coiled segments of the long sigmoid. An adult-sized proctosigmoidoscope is well tolerated by children 3 years of age or older. It is emphasized that in the newborn the anterior peritoneum extends to within 1.25 cm (0.5 inch) of the anus, whereas posteriorly the peritoneal reflection is rather high.

The embryologic, pathologic, and clinical features as well as the treatment of imperforate anus are well discussed by Arnheim, and Rosenblatt and May, and Brynjulfsen, who believe that an operation should not be delayed too long in the uncomplicated cases. On the other hand, Rhodes re-emphasized his former teachings (*Am J Surg*, 1934, 24 828) that operation for imperforate anus should be delayed for several days to give the terminal bowel sufficient time to descend as far as possible. In some cases the utmost descent takes place in 48 hours, while in others it will not occur until the infant is 5 days old. Rhodes also believes that virtually all of the newborn can be operated upon successfully through the perineal approach, "perhaps there may be a thousandth case that will require colostomy." It should be pointed out that colostomy is generally advised if the rectal pouch is more than 2 cm above the perineum or when a fistula to the urinary tract exists. Liburt reported a successful anorectoplasty with a 3-year follow-up, in which he utilized the sigmoid colon as a new rectum and anus.

Rhoads (*Ann Surg*, 1948, 127 552) reported 2 instances in which the simultaneous abdominal

and perineal operation for imperforate anus of Type III of the Ladd and Gross classification (*Am J Surg*, 1934, 23: 167) was successfully performed.

A case of complete congenital atresia of the transverse colon was reported by Potts. A successful side-to-side isoperistaltic anastomosis was performed with No. 00000 silk used throughout. The patient made a smooth recovery. Roentgenography by means of an opaque enema performed on the nineteenth postoperative day showed that the lumen of the colon had enlarged considerably. Potts believes that his is the first instance of this anomaly in which the infant survived surgical interference.

A case of duplication of all segments of the colon (colon duplex), including the cecum and rectum, was reported by Weber and Dixon. Both colons seemed to be complete morphologically and had a common mesentery. The colon without external communication was filled with fluid and calcareous material, displacing the other colon and rectum.

Duplication of the colon is rare as contrasted with the relative frequency of duplication of the small bowel (77). Parenthetically, only 1 case of triplication of the colon has ever been reported (Gray, A. W., *Arch Pathol*, 1940, 30: 1215).

Scott and Serenati believe that megacolon is a symptom complex rather than a disease entity. Mechoyl bromide was successfully employed by Peterman in 11 of 12 children with congenital megacolon. Swarts believes that conservative medical therapy should be maintained for a year in this condition and that no patient under 5 years of age should be treated surgically. Scott, utilizing the spinal anesthetic motor test, believes that when this test is effective, previous conservative therapy should be continued. In a few selected patients sympathectomy was advised if spinal anesthesia brought about a dramatic temporary effect. When the spinal anesthesia test is ineffective, the condition is classified as dolichocolon and colonic resection is carried out. Scott prefers a left hemicolectomy and a lateral anastomosis in order to produce the widest possible stoma. Swarts, and Dixon and Benson (76) do not consider sympathectomy a good operative procedure, but regard colectomy the surgical procedure of choice. Dixon favors the exteriorization procedure, and calls attention to the temporary distressing intestinal dysfunction which may appear several weeks after operation. Plain roentgenograms of the abdomen show moderate dilatation of both the small and large bowel which is often segmental. This condition seems to be pro-

duced by spasm and functional derangement of the normal peristaltic activity of the intestine. The administration of belladonna in adequate dosage affords early and adequate relief. At the Mayo Clinic belladonna is given routinely for several months after this type of operation.

D'Antoni encountered 73 juveniles ranging from 6 months to 12 years with amebiasis who presented manifestations differing from those of adults. These children had (1) a muddy or yellowish-tinged complexion, (2) large and tender liver, (3) changes in personality (well behaved children became irritable, sullen and unm manageable), and (4) capricious and sometimes insatiable appetites. Slight constipation was frequent. Diarrhea was present in a few patients and mild dysentery in a few others. The diagnosis was made in the laboratory in all 73 patients, with a doubtful one. Usually, the diagnosis was made from aspirated material secured at sigmoidoscopy. Parents or others in close contact with the children were always found to have amebiasis. Adequate therapy produced prompt improvement in the symptoms (see chapter dealing with diarrhea and dysentery).

D'Antoni also indicated that amebiasis may be associated with neurosis, anxiety states, cholecystitis, appendicitis, and peptic ulcer.

As stated in the chapter dealing with large bowel neoplasms, exclusive of the first year of life approximately 3 per cent of children have adenomatous polyps (118). Occasionally, the familial type of adenomatosis is observed in juveniles (76).

Bonelli reviewed the literature and found 14 cases of carcinoma and 76 cases of sarcoma of the small and large bowel in individuals up to 19 years of age. Sarcomas occurred predominantly in the small bowel and infrequently in the colon and rectum, they also occurred in the duodenum. Carcinoma was prevalent in the colon especially in the rectum (70 cases). Carcinoma of the colon and rectum ranked first among the malignancies of the alimentary tract. Of the carcinomas were polypoid, ulcerative, infiltrative, and stenosing. Microscopically, the neoplasms were adenomatous, sarcomatous, and undifferentiated.

The diagnosis of colonic neoplasms was based on history, physical examination, digital rectal examination, anoproctosigmoidoscopy, and roentgenography. About 75 per cent of the lesions were visualized instrumentally and the remaining lesions situated above the reach of the sigmoidoscope were diagnosed with the aid of a barium contrast barium enema. The treatment was surgical resection with immediate anastomosis or colostomy followed by resection.

MISCELLANEOUS

Sullivan and King (259) confirmed the efficacy of resin of Podophyllum for the eradication of condylomata acuminata. However, they changed the original method of treatment recommended by Kaplan (*N Orleans M & S J*, 1942, 94 338), using 20 per cent of the drug in 95 per cent of alcohol instead of in the suspension of oil. Marks uses a 15 per cent concentration of Podophyllum in compound tincture of benzoin. Sullivan and Blanchard (257) believes that resin of Podophyllum exerts its action on the cell metabolism (in contrast to drugs which produce a fixing or coagulation effect) and that podophyllotoxin is probably the substance responsible for the cytotoxic effect.

Kushlan presented a historic and clinical review of hereditary hemorrhagic telangiectasia, as well as its successful treatment with rutin which is supposed to act by decreasing capillary fragility and by increasing the strength of the muscular endothelial wall of the telangiectases.

Marshak discussed the extracolonic pelvic pathologic processes which because of their proximity may produce roentgenologic defects in the rectosigmoid.

Browne pointed out that mineral oil interferes with the absorption of vitamins and minerals, with normal physiologic processes of the intestinal tract, and with anal hygiene. Alvarez (7) called attention to the fact that when mineral oil is administered in the form of a fine emulsion about one-half of it goes through the wall of the bowel and goes on into the liver. It appears that the indiscriminate use of mineral oil can be dangerous and one should be aware of its possible deleterious effects.

In the past there have been reported several fatal accidents in which death resulted from an explosion of intestinal gas during electrocoagulation procedures. To eliminate the dangers of explosions, Marchand described a method of electrosurgery which could safely be used in the terminal portion of the colon. The essential feature is contact coagulation by means of an instrument which is fastened in place before the current is turned on and is not withdrawn until the current has been turned off, this averts the possibility of a spark at the making or breaking of the contact. It should be noted that Bierman's coagulation electrodes which are fastened to the lesion by means of suction accomplish the same purpose. Furthermore, it is believed that explosions of intestinal gases can be avoided easily by the employment of suction simultaneously with electrocoagulation. Arnous designed an in-

genious proctoscope through which an incombustible gas (nitrogen or carbon dioxide) is made to pass through a 3 way stopcock, flooding the region of the spark. This gas is said to form a barrier between the intestinal gasses and the external air (creating an inert atmosphere) and thereby prevent the formation of an explosive mixture.

PILONIDAL (SACROCOCYGEAL) DISEASE

Certain facts about pilonidal disease which became evident during World War II and trends in the choice of surgical procedures for this condition were discussed by Turell (272). It is now apparent that trauma plays an important role in the activation of pilonidal lesions. Hyperhidrosis and lack of ideal personal hygiene imposed by training and battle conditions have been important in the initiation of pilonidal infection. Surgical specimens removed at initial operation yielded hemolytic and nonhemolytic staphylococci and streptococci, whereas organisms of the colon bacillus group were almost never found. Similar findings were obtained when the subcutaneous tissue juices of the buttocks, as far out as 2 cm from the line of excision of pilonidal cysts, were studied bacteriologically. These observations suggested that sulfonamides and antibiotics have a definite place as an adjunct to surgery.

A comparative study of chemotherapeutic agents in the primary closure of pilonidal wounds by Hamilton and Cattanach showed that the best results were obtained with locally applied penicillin combined with orally administered sulfadiazine. Successful healing was noted in 93.8 per cent of 32 patients so treated. Patients receiving penicillin intramuscularly in doses between 20,000 and 25,000 units every 3 hours showed no significant superiority in wound healing over those who received no chemotherapy. However, in a few cases of incipient postoperative wound infection, a dosage of from 60,000 to 80,000 units of penicillin, administered parenterally every 3 hours, was effective in aborting infection when smaller doses of this antibiotic were ineffective. Turell (272) reported that penicillin administered early and in large doses may have been effective in preventing abscess in some cases of cellulitis in the pilonidal area.

In cases of abscess the best results have followed a simple surgical procedure (272) which consists of the evacuation of pus, necrotic material, and, frequently, tufts of hair through a generous incision, as well as irrigation of the abscess cavity with normal saline solution. The

roof of the cavity is then removed, hemostasis is obtained by gentle pressure, and the cavity is packed lightly with gauze (or gelatin sponge) which has been previously soaked in a solution of penicillin. By comparison with the method of crucial incision and drainage only, the wide unroofing of the abscess cavity is believed to be a far superior procedure.

Good results from conservative sclerotherapy in acute, chronic, and recurrent cases of abscess were reported by Shafiroff and Doubilet who employed a penicillin-sodium morrhuate solution (100,000 units of penicillin to 5 c.c. of 5 per cent solution of sodium morrhuate).

The marsupialization (Buie) technique for cysts and sinuses was discussed by Henning and Dempsey, and by Todaro and Prag.

A cutaneous flap procedure utilizing a transverse or lateral incision was described by Berman. After proper scrubbing of the operative area with soap and water, the sinus was excised widely and completely through an elliptical or longitudinal incision. Transverse incisions were then made through the wound and the flaps undermined. The longitudinal or horizontal wounds were closed. The lateral wounds were left open for drainage in infected cases, while in clean cases the wounds were closed loosely. Berman believes that his cutaneous flap technique permits mobility of the wound at a higher level, and releases all tension on the longitudinal suture line. This, in turn, puts the suture line of the 2 lower flaps at rest and allows these flaps to move as a unit, this prevents poor healing of the caudalmost angle of the horizontal or longitudinal wound. This technique aims to combine some of the desirable features of the closed techniques and the open procedures.

A method of primary closure without flap formation is described by Larkin. A narrow strip of skin is excised in the midline which includes the ostia of the cyst as well as scars from previous incision and drainage procedures. The cyst and adjacent subcutaneous tissues are removed to denude the sacrococcygeal and gluteal fascia bilaterally and undermine the skin widely. Number 30 stainless steel sutures are placed through the skin 0.5 inch apart on the gluteal and sacrococcygeal fascia, which when tied over a gauze dressing tend to close the dead space. The skin is reapposed with No. 30 stainless steel wire vertical mattress sutures. All sutures are removed on the seventh postoperative day. Primary healing was obtained in 90.9 per cent of 66 patients who had not been operated upon previously and in 71 per cent of 21 patients with re-

current lesions. All patients had received penicillin parenterally.

For the treatment of uninfected pilonidal cysts the musculofascial flap techniques with primary closure of the wound came into vogue during World War II, although the theoretic advantages of such procedures were apparent to Ottenheimer in 1933 (Ottenheimer, E. J. *Ann. J. Surg.*, 1933, 2: 120). Pope described a sliding gluteus maximus muscle graft technique, and Ziegler *et al.* described a sliding fascia procedure. For the details and illustrations of these operations the reader is referred to the drawings of the original article.

Holman has simplified the musculofascial techniques. His procedure is quite akin to the one described by Shute *et al.* (*Ann. Surg.*, 1941, 118: 706). In short, the pilonidal cyst is excised en bloc through an elliptic incision directed lateromedially. The fascia overlying the gluteus maximus muscle on both sides, together with a thin layer of muscle tissue, is mobilized sufficiently to permit approximation of the outer flaps without tension. The outer musculofascial flap are united in the midline overlying the coccyx and the lower sacrum by from 4 to 8 interrupted No. 0 chromic catgut sutures. These sutures include bites of the midprecoccygeal and presacral fascia with a view to obliterating the dead space. Nonabsorbable sutures are not used as these are undesirable in this area. The skin is approximated by a continuous subcuticular stitch of nonabsorbable suture material which is removed in 7 or 8 days. The inferior angle of the wound is closed meticulously (epithelial edge to epithelial edge), while 2 cm. of the cephalad portion of the wound are left open for the escape of blood and serum. This is an important point of the technique. One of us (272), in performing the Shute procedure, meticulously closed the inferior angle of the wound and left the remainder of the wound open for a period of about 48 hours with the insertion of a gauze wick. This gauze packing was placed between the skin edges following the introduction of the skin sutures which were left untied from 36 to 48 hours. After the removal of the gauze the sutures were tied to approximate the skin edges. It was surprising to observe a large amount of hemorrhagic serum in the dead space at this time. The application of the primary closure to the middle and cephalad portions of the wound had not increased the time of effective healing.

During operation trauma to the tissue was meticulously avoided, even retraction was used so as not to injure the delicate and valuable adipose tissue. Clamp on bleeding vessels

are rarely used. Patience and digital pressure usually stop the bleeding. Chemotherapy is used before and after operation. The patient lies on his abdomen or sides and may stand to urinate, lying on the back and sitting is forbidden for over a week.

The occurrence of a rare complication, namely, subphrenic abscess, following primary closure for pilonidal cyst was reported by Hurwitt.

Holman called attention to the acquired type of recurrence. Dimpling of the skin with a subcutaneous sinus penetrating the deep tissues may occur in the scar. Hairs from the walls of the dimple are directed inward which act as a foreign body perpetuating infection. Simple excision of such dimples is curative.

Skin grafting of the wound, employing an intermediate or a split-thickness skin graft after excision of large recurrent pilonidal cysts, may be done advantageously (131, 272). The freshly exposed area apparently is a good base on which to place a skin graft. It should, however, be pointed out that the grafted skin in the sacrococcygeal area is affected easily by slight trauma to present excoriation or fissures.

On the basis of prewar civilian and considerable military experience during World War II, one of us (R.T.) believes that the open operation with excision en bloc is the safest procedure in the hands of the average surgeon. However, this surgical procedure leaves a thin and wide scar over bone structures without an intermediate protective subcutaneous layer of fat. This in turn renders the scar vulnerable to trauma.

On the other hand, the primary closure techniques are still in the process of perfection. At the present the musculofascial techniques, such as that described by Holman, are the preferred procedures especially for treatment of the large cysts or sinuses. The complications following primary closure, which appear to be due to bleeding, infection, and to the use of nonabsorbable suture material, can be dealt with easily by converting the closed wound into an open one. Experience has shown that when these wounds are laid open they heal exceedingly fast (healing is much more rapid than that following primary open technique excision en bloc), probably because of the increased vascularity of the muscle and the mobilization of the gluteal fascia which allow faster cicatricial contracture of the wound. The reconstructive primary closure of the pilonidal wound is a useful procedure when properly indicated and performed (228).

Smith (*J Im M Ass*, 1948, 136: 973) is apparently the first to report the occurrence of

"true" pilonidal cysts in the anterior part of the perineum.

SURGERY OF THE HEAD AND NECK

HEAD

Epithelial Tumors Associated with Developmental Cysts of the Maxilla EDWARD C STAFNE *Oral Surg*, 1948, 1 887

Cysts of the jaws that are of developmental origin are most often lined with a fairly even, uniform layer of epithelium. In a few instances variation from this smoothness of the wall may be manifested by the occurrence of thickening or the presence of mural or papillary growths of the inner wall of the cysts.

In the 3 cases reported in the complete paper, the entire cavity of the cyst had become filled with an epithelial tumor. Two of these epithelial tumors occurred in dentigerous cysts and 1 occurred in what appeared to be a globulomaxillary cyst.

Some of the results of the study of 3 epithelial tumors in the maxilla have been given. These 3 tumors presented many similar features. Two of them occurred within the fibrous tissue capsule of dentigerous cysts and the third occurred in the interseptal bone between the maxillary lateral incisor and the canine tooth. The location of the third at once aroused speculation as to whether it was derived from epithelial remnants in the closure of the globular and maxillary processes, similar to those from which globulomaxillary cysts are derived.

A glandular arrangement and formation of acini were common to all 3 tumors, but the presence of mucin was not demonstrated. A clearly defined hyaline-like ring was seen about many of the glandular spaces. The nature of the substance of these rings was not determined. The thought was entertained that the rings might be evidence of an attempt to form an enamel matrix.

The roentgenologic findings were of interest in that they suggested conditions other than those found. Radiopaque objects which one would ordinarily presume to be calcified dental structures proved to be calcareous deposits in the stroma.

Although the 2 tumors that developed within the dentigerous cysts no doubt had their origin from odontogenic epithelium, they lacked the typical features of epithelial tumors derived from that source. What inhibitory influence the fluid of the cyst may have had on the tumor growth is problematic.

EYE

The Fascia of the Orbit Its Anatomy and Clinical Significance RICHARD G SCOBEE *Am J Ophth*, 1948, 31 1539

The fascia of the orbit is more or less continuous. The dura mater investing the optic nerve divides at the apex of the orbit into an outer layer, the perior-

bita, and an inner layer which continues along the optic nerve. The periorbita is confluent with the periosteum of the facial bones and at their junction they form a ridge known as the arcus marginale. The septum orbitale extends from this ridge around the orbit to the palpebral fissure.

The annulus of Zinn is intimately fused with both the periorbita and dura at the apex of the orbit. The dura which ensheaths the optic nerve in its orbital course fuses with the fascial capsule (Tenon's) which encases the globe at the point of exit of the optic nerve. The middle third of the capsule is pierced by the oculorotary muscles passing toward their scleral insertion. The capsule is prolonged backward at these points along each muscle. This muscular fascia ensheaths each muscle completely and stretches as a membrane between adjacent margins of the rectus muscles. Division of this membrane is necessary to obtain the maximal effect in recession operations. Offshoots of the muscle sheaths become attached to the periorbita to form check ligaments. These must be sectioned to assure satisfactory results in muscle surgery.

FRANK W NEWELL, M D

Horizontal Concomitant Strabismus EDMUND B SPAETH *Am J Ophth*, 1948, 31 1553

True horizontal concomitant squint is the classical, alternating type wherein the patient has the same degree of squint for near and for distance with the objective and subjective angles being the same, the refractive error practically equal in each eye, and not related to the squint or to the convergence-accommodation ratio. Except in this pure type of strabismus congenital disturbances of the vertical rotators play a profound role in the development of convergent and divergent squints of all types. The unmasking of the vertical component and the identification of muscles involved is basic to the diagnosis.

Inferior oblique muscle overaction may occur in accommodative strabismus without demonstrable paresis of the contralateral synergist. Oblique muscle overactions are more common than similar involvement of the vertical rectus muscles. It is not always possible to state that the lateral concomitant deviation is due to a paresis of a vertical acting muscle, or secondary deviation of the synergist, or overaction of the direct antagonist of a paretic muscle. In such cases in which the vertical anomaly is contributory to the lateral concomitant strabismus, treatment by orthoptics is not indicated and the treatment is surgical, preferably before the age of four. The greater deviation, whether horizontal or lateral, should be first corrected. Satisfactory single binocular vision with fusion cannot be obtained as long as the vertical component is present to an ap-

preciable degree. The sequence of surgical procedures of the vertical methods which gives the best results is as follows: (a) a recession of the overacting synergist or a resection of the paretic muscle, (b) reversal of the sequence of (a), (c) recession of the overacting direct antagonist.

FRANK W. NEWELL, M.D.

Operative Treatment of Vertical Tropias B. I. PAVNE *Am J Ophth*, 1948, 31: 1217

The author cites that the surgical relief from the discomfort of vertical tropias has progressed remarkably since Duane and his pupil, White, performed one of the first tenotomies on the inferior oblique muscle. He stresses the necessity of an accurate diagnosis of the muscle or muscles involved in vertical tropias. To arrive at the proper outcome of surgery he suggests a routine examination consisting of:

1. History—general and ophthalmic
2. Visual acuity and accommodation determinations without and with glasses
3. Muscle balance and fusion tests
4. Refraction and correction with glasses
5. Orthoptic treatment
6. Operation and follow up

He stresses the value of the estimation of the phoria or tropia in the primary position and in the 6 cardinal directions of gaze. Eye dominance is determined because most surgeons prefer to operate on the nondominant eye. Orthoptic exercises should follow surgery if the degree of fusion warrants it.

The author also stresses the point that if the patient has no symptoms and is content with his appearance he should be let alone.

The operative objective in the correction of vertical tropias is to give horizontal alignment to the visual axes of the two eyes. This may be done in one of three ways or a combination of the three:

1. By strengthening the weak or paralyzed muscle by a shortening operation
2. By weakening the contralateral synergist by tenotomy or recession
3. By weakening the antagonist of the same side by recession or tenotomy

The author states, after citing 6 cases, that each millimeter of recession of the inferior oblique muscle gives approximately 2.5 prism diopters of correction. In conclusion he states that:

1. Carefully planned operations for the relief of vertical tropias are successful if the diagnosis is correct
2. A clear understanding of the muscle or muscles involved is essential
3. The type and extent of operation will be determined by the points brought out in examination
4. Injury to the neighboring structures should be avoided

J. WOODRILL OVERTON, M.D.

Implant of a Vitallium Tube in the Treatment of Stenosis of the Lacrimal Duct VITO L. ROCCA *Arch Ophth*, Chic, 1948, 39: 657

The author advocates the insertion of a vitallium tube into the bony lacrimal duct through the lower part of the sac.

Under local anesthesia an incision is made 1 cm. long, beginning at the lower edge of the intercanthal ligament and curving downward. A probe is used as a guide. An incision is made in the sac and the bony canal curetted. The tube is inserted and secured to the periosteum by suture.

The operation is simple, it can be performed despite of mucosal atrophy or infection and gives excellent results.

EARL H. MERZ, M.D.

Intravitreal Injection of Penicillin: Study on the Levels of Concentration Reached and Therapeutic Efficacy ARNOLD SORSHBY and JOSEPH L. CAR *Brit J Ophth*, 1948, 32: 857

The authors discuss the intravitreal injection of penicillin. Their studies were conducted with a view to assessing the levels and persistence of penicillin injected intravitreally and to determine the efficacy of this procedure in controlling experimental infection of the vitreous.

In the early days of penicillin therapy direct injection of penicillin into the vitreous was considered as a possible method of treatment because it was believed that penicillin injected systemically did not penetrate into the interior of the eye. Early reports of penicillin destroyed the eye but crystalline penicillin was well tolerated (although damage to the retina did ensue).

The results of the authors' experiments, however, were not encouraging. Only 2 of the 3 rabbits which were treated 3 hours following infection, and only 1 (or possibly 2) of the 3 which were treated immediately after infection can be regarded as having eyes with good function, clinically. In all the remaining animals the infected eyes were lost. Although penicillin influences the course of the infection once a vitreal injection of 5,000 units is not sufficient to overcome fully a heavy experimental infection even when it is administered 3 hours following infection or at the time of infection. If treatment is begun 3 hours after infection, panophthalmitis can be prevented, but organization of the vitreous destroys the function of the eye.

It is concluded that adequate antibiotic levels do not persist in the vitreous for 36 hours and probably 48 hours after direct intravitreal injection of 5,000 units of crystalline penicillin in 0.05 ml. of vitreous.

In these experiments the vitreous was infected with 1,000,000 organisms of staphylococcus aureus.

Briefly stated, the authors conclude that 5,000 units of crystalline penicillin injected into the vitreous had some slight effect if administered 3 hours following infection, panophthalmitis was prevented but the vitreous became organized and infection was begun 3 hours after infection or at the time after infection. 3 (and possibly 4 or 6) rabbits could be considered as clinically functionally cured.

It has not been determined that the therapeutic level in the vitreous could be maintained by conjunctival injection so that direct intravitreal injection of penicillin is necessary.

JOSEPH L. CAR

The Control of Experimental Infections of the Anterior Chamber and of the Vitreous by Subconjunctival and Retrobulbar Injections of Crystalline Penicillin in Doses of 1,000,000 Units
ARNOLD SORSBY and JOSEPH UNGAR *Brit J Ophth*, 1948, 32 873

The authors' report concerns the control of experimental infections of the anterior chamber and of the vitreous by subconjunctival and retrobulbar injections of crystalline penicillin in doses of 1,000,000 units, the object being to determine whether more consistent results can be obtained, and whether the frequency of injection can be reduced. Infection was induced by introduction into the anterior chamber or into the vitreous of a suspension of 50,000 staphylococcus aureus organisms in 0.05 ml of saline.

It was found that infections of the anterior chamber can be controlled by subconjunctival injections of penicillin if adequate doses are administered. With doses of 20,000 units, injections at intervals of about 6 hours were necessary. With doses of 1,000,000 units, two or three subconjunctival (or possibly retrobulbar) injections at intervals of 24 hours were required to control a fairly severe, although not fully established, infection of the anterior chamber.

The following results were obtained after experimental infection.

Infection of the anterior chamber. Of 9 rabbits with infection of the anterior chamber, 5 were treated by subconjunctival injection—3 within 4 hours after infection and 2 within 24 hours after infection, 4 rabbits were treated by retrobulbar injection—2 within 4 hours after infection and 2 within 24 hours after infection. The 3 rabbits treated by subconjunctival injection 4 hours after infection made an uninterrupted recovery, the 2 rabbits treated 24 hours after infection responded satisfactorily, but the infection was more prolonged and the sequelae was more marked. Of the 2 rabbits treated by retrobulbar injection 4 hours after infection, one recovered completely, the 2 treated 24 hours after infection did not recover well.

Infection of the vitreous. Of 9 rabbits with intravitreal infection, 4 were treated by subconjunctival injection and 5 were treated by retrobulbar injection. The doses and time intervals were all similar to those employed for infection of the anterior chamber. The course in all control rabbits was unfavorable. Two rabbits first treated by subconjunctival injections 4 hours after infection responded quite well, however, in the 2 rabbits first treated 24 hours after infection, disorganization of the eyeballs resulted. Three rabbits first treated 4 hours after infection by retrobulbar injection also responded to treatment, but 2 rabbits which were first treated 24 hours after infection failed to respond to treatment.

Rabbits which had been treated 4 hours after infection were given a second dose of penicillin 20 hours later, rabbits treated 24 hours after infection were given subsequent doses at 48 hours and again at 78 hours. The results in all control animals were unfavorable.

JOSHUA ZUCKERMAN, M D

Distribution of Penicillin in the Eye After Injections of 1,000,000 Units by the Subconjunctival Retrobulbar and Intramuscular Routes
ARNOLD SORSBY and JOSEPH UNGAR *Brit J Ophth*, 1948, 32 864

Studies have been carried out on the distribution of penicillin in the eye after injections of 1,000,000 units by the subconjunctival, retrobulbar, and intramuscular routes. Adequate therapeutic levels could be obtained intraocularly by the injection of large doses of penicillin subconjunctivally, or by systemic administration of massive doses. The levels reached and maintained by subconjunctival injection were higher than those obtained when the drug was administered by other routes. Subconjunctival injections yielded higher and more persistent levels when the penicillin was dissolved in a 1 to 1,000 solution of epinephrin hydrochloride instead of in water.

The administration of a dose of 50,000 units subconjunctivally yielded not only higher but more persistent intraocular levels of concentration than a dose of 20,000 units.

The investigation proved that penicillin administered systemically penetrates the interior of the eye in adequate therapeutic levels if sufficiently massive doses are employed. However, local administration of penicillin by the retrobulbar or subconjunctival route yields distinctly higher intraocular levels and better maintenance than injection of a corresponding dose intramuscularly. Moreover, when epinephrine is used as a solvent higher intraocular levels of concentration are maintained.

Experimental investigation with rabbits proves that when a dose of 1,000,000 units of crystalline penicillin in a 1 to 1,000 solution of epinephrin is injected subconjunctivally, an adequate level is reached and maintained not only in the aqueous but also in the vitreous for at least 48 hours. The high level reached and maintained in the vitreous by this dose and mode of administration is noteworthy, for neither massive intramuscular injections nor injections of 50,000 units (in adrenalin) subconjunctivally give high or persistent levels of penicillin in the vitreous. Direct intravitreal injection of penicillin is unnecessary.

JOSHUA ZUCKERMAN, M D

Controversial Points in Penicillin Therapy of Ocular Diseases
LUDWIG VON SALLMANN and JEANETTE DI GRANDI *Arch Ophth*, Chic., 1948, 39 752

The present study extended over several phases of the parenteral and local use of penicillin in ophthalmology. The failure of penicillin to pass the blood-aqueous barrier in adequate amounts during systemic therapy could not be related to a selective transfer through the ciliary epithelium or to a restraining effect of the epithelial membrane, it was shown, rather, to be related to the functional states of the capillary wall, to the steep decrease in the drug level in the blood by rapid renal excretion and, in a moderate degree, to the speed of absorption of the substance from the aqueous.

sensitivity is decreased. A diffuse opacity resembling a spider occupies the entire cornea, with exception of the peripheral 1 or 2 mm. In early cases, interlacing gray lines and fine nodules can be seen with the unaided eye or with the loupe. The biomicroscope reveals many lines, with a myriad of fine deposits in their interstices. All the layers of the cornea are affected but there is a greater preponderance in the anterior third. During the acute stage, ulceration of the epithelium may be present. In uncomplicated cases no blood vessels are present in the stroma.

Pathologic examination reveals a hyalinlike material deposited within and outside of the corneal lamellae and in the epithelium. The intralamellar deposits are tiny, extralamellar deposits are larger. The deposits are concentrated in the anterior layer of the corneal stroma. Bowman's membrane is usually missing. The epithelium is disorganized.

The lattice type of dystrophy is differentiated from the granular type of familial dystrophy by the presence of "lines" in the lesion, by the relatively early loss of vision, and by the defective corneal sensitivity. It is differentiated from the macular types of corneal dystrophy by the lines and the nodules, its central location in the cornea, and its dominant inheritance. There is no satisfactory treatment for corneal dystrophy, but keratoplasty may prove effective.

To the report of 100 cases in the literature, the author adds 5 cases, one of which occurred in a patient 2 years of age, the youngest patient with this condition whose case has been reported up to the present time.

JOSHUA ZUCKERMAN, M D

The Rupture of the Zonule in Intracapsular Cataract Extraction—A New Method DANIEL B KIRBY *Brit J Ophthalm*, 1949, 33 3

In intracapsular extraction of cataracts the break in the zonule occurs at its union with the lens capsule. Pressure and traction are best applied simultaneously. Pressure should be applied by a relatively pointed instrument such as the Jamison hook, which he has adapted for this purpose. After the incision, sudden sharp point pressure is made just inside the limbus at equidistant points (6, 8, and 4 o'clock), indenting the cornea 2 to 3 mm, and causing the incision to gape diametrically opposite.

Since Kirby believes the sliding or, even better, the rotational delivery of the lens is less disturbing than the tumbling procedure, he prefers the grasp above just anterior to the equator. This requires a well dilated pupil or a complete coloboma of the iris. A horizontal tangential application is made which allows ready rotation to either side along the curve of the equator. With this method the surgeon can see better what he is doing, particularly when the corneal flap is lifted, and he can lift the lens away from the hyaloid and vitreous. With such direct vision, pressure can be directed to the area of zonule under tension, rupturing it more easily than if more pressure was directed to a relaxed area.

In subluxation of the lens, or in cases in which the zonule proves resistant or resilient, it can be stripped from its attachment by direct rupture. With the capsule grasped above, vertical traction lifts the zonule 3 mm away from the relaxed hyaloid. This may be combined with downward traction for better exposure, then a light touch or two with the blunt elbow of the lens hook will cause the zonule to rupture in part, producing a dehiscence at the equator which is extended by rotation of the lens. This new maneuver is indicated when pressure, traction, and rotation are insufficient. Proper illumination should be secured by a parallel beam spotlight, and the corneal flap should be elevated to afford a direct view of the lens equator.

Kirby uses his own special instruments which are described and illustrated.

JAMES E. LEBENSOHN, M D

Preliminary Note on the Treatment of Hypopyon Ulcer with Crystalline Penicillin in Adrenalin in Doses Exceeding 50,000 Units Injected by Subconjunctival or Retrobulbar Routes ARNOLD SORSBY and JOSEPH UNGAR *Brit J Ophthalm*, 1948, 32 878

The authors present a preliminary report on the treatment of hypopyon ulcer with crystalline penicillin in adrenalin in doses in excess of 50,000 units which are injected by the subconjunctival or retrobulbar routes. It was found that doses greater than 50,000 units have the advantage of giving a higher concentration of penicillin intraocularly and that this concentration persists for a longer period of time than when smaller doses are given. With subconjunctival injections of 1,000,000 units in adrenalin the intervals between doses could be increased from 6 to 48 hours. Doses of 500,000 units of crystalline penicillin in adrenalin can be used safely at intervals of 24 hours.

It is concluded that results in the treatment of hypopyon ulcer with crystalline penicillin are distinctly promising, both as to a satisfactory end result and to rapidity of cure, when the drug is administered in doses of 500,000 units in 0.5 milliliters of (1:1000) epinephrine solution at intervals of 24 hours.

Although theoretically less effective, the injection of such doses by the retrobulbar route appears to present clinical possibilities.

JOSHUA ZUCKERMAN, M D

Miotic and Antiglaucomatous Activity of Tetraethyl Pyrophosphate in Human Eyes W. MOR-TON GRANT *Arch Ophthalm*, Chic., 1948, 39 579

Tetraethyl pyrophosphate is a new anticholinesterase chemical which is a colorless, water soluble, lipid soluble liquid.

In normal eyes it was found to be comparable to physostigmine in miotic activity. In glaucomatous eyes, it lowered the intraocular tension when used in the strength of 0.1 per cent, the vehicle being peanut oil.

When renal clearance was prevented, a high and sustained penicillin content of the blood secured satisfactory concentration of the drug in the aqueous. The importance of capillary permeability was shown by the great change in the aqueous-blood ratio of penicillin in various stages of a nonbacterial endophthalmitis.

The best opportunity for utilizing the benefits of systemic penicillin treatment of severe ocular infections is offered in the administration of massive doses in the acute stages, aided by the simultaneous local instillation of vasodilators in cases of less violent inflammations, as an adjuvant, may be considered the use of substances which decrease the renal output of the antibiotic by competing for the same excretory mechanism. General treatment may effectively supplement local penicillin therapy when the infective foci are not easily accessible by local methods.

In the study of the surface application of penicillin, the continuance of penicillin activity was usually observed in the tears for 8 hours after one instillation of drops or ointment, suggesting that the frequency of treatment of external infections can be reduced without excessive tearing or secretion.

Several aspects of ocular iontophoresis with penicillin were studied. The claims of poor conduction of the compound and of a substantial destruction of the antibiotic by the shift of the hydrogen ion concentration, due to the products of electrolysis, were disproved in regard to corneal iontophoresis with applicator tubes of sufficient capacity. It was shown that the high penicillin content of the cornea and aqueous was procured by the effect of the flow of the current from the cathode on the barrier properties of the epithelium. When solutions of low tonicity were employed, much more of the substance was observed in the aqueous, both after iontophoresis and after corneal bath, owing, however, to damage to the corneal epithelium.

In vitro and in vivo experiments gave evidence that better results could be expected from transient high peak drug levels when the infecting organism was of medium sensitivity to penicillin. The observations appear applicable to iontophoresis, as well as to other means (cotton packs, injections) of obtaining a high penicillin content in the eye.

The superiority of introducing penicillin directly into the vitreous in the treatment of infections of the posterior segment was demonstrated. A dose equivalent to 1,000 units of the commercial crystal line penicillin was used, without causing histologically recognizable retinal lesions. A dose of 1,000 units is about ten times the amount which was effective in checking various experimental infections of the vitreous. FRA F W NEWELL, M.D.

Infection of the Cornea Due to Herpes Simplex An Experimental Study JAMES L. MCGRAW *Arch Ophthalmol*, Chic, 1948, 40: 531

The lesion of herpes simplex on the cornea is characterized by the formation of minute opacities of the

epithelium, which may lead to vesiculation and necrosis, and the ultimate typical picture of a dendritic ulcer. The infection may accompany herpetic lesions in other parts of the body—the lips, genital area, and skin. There is a decided tendency toward recurrence.

The usual onset is acute, with pain in the eye and the appearance of a haze of fine granular spots in the epithelium. This is associated with a fine bed of the epithelium and the development of craters and fissures, surrounded by closely packed minute opacities. The lesion may assume a form similar to superficial punctate keratitis or dendritic keratitis. The epithelium in the region of the lesion may be loosely on Bowman's membrane, and may be broken away (epitheliolysis). The process may persist for several days or weeks, and finally clear, leaving no trace. The lesions, however, may recur and coalesce to form an irregular ulcer, the dendritic ulcer. The zigzag line of ulceration rarely exceeds 1 mm in breadth and shows many side branches at the ends of which have beadlike nodes. At the end of its development, the process may recede, and complete healing may take place without a scar. In all herpetic involvement of the cornea, there is hypoaesthesia.

The present investigation has the primary purpose of determining the effect of penicillin, streptomycin, and tyrothricin on the virus of herpes simplex. Special reference is made to its manifestations in the eye. The study was carried further in the attempt to corroborate or disprove some of the other advocated therapeutic measures.

Penicillin is ineffective in combating the virus of herpes simplex in mice, in vivo and in vitro. Streptomycin in high concentrations seems to have a slight inhibitory effect on the virus of herpes simplex in vivo. However, it fails to destroy the virus completely. Tyrothricin, in dilution of 33 mgm per 100 cc, is not a beneficial therapeutic agent. It is also a hyperimmune serum, intravenous sodium iodide, and cathode iontophoresis of sodium iodide. Contraindicated are anode iontophoresis of 1 per cent zinc sulfate, and the local application of 1 per cent iodine in 70 per cent alcohol. Caution is advised in the dendritic ulcers, with 20 per cent zinc sulfate of definite value in the healing of dendritic ulcers in rabbits. MICHAEL FOURMANT, M.D.

Lattice Type of Hereditary Corneal Degeneration Report of 5 Cases, 1 of Which Occurred in a Child of 2 Years IRIDIPICK, C. S. *Arch Ophthalmol*, Chic, 1948, 40: 151

The author discusses the lattice type of hereditary corneal degeneration. This type of corneal dystrophy is bilateral, chronic, slowly progressive, and of hereditary dominance. The etiological factor is unknown. It begins in the first decade of life. In youth the condition presents itself as current erosions of the corneal epithelium, photophobia, lacrimation, and mild conjunctivitis. In adult life, attacks recur frequently, and vision progressively declines. In advanced stages, the

NECK

The Treatment of Thyrotoxicosis SIR CARRICK ROBERTSON *Lancet*, Lond, 1948, 2 675

The author reports 350 cases of thyrotoxicosis in patients who were treated during the period from 1945 to 1947. About one-third of the patients were treated with thiouracil. Of those under 21 years of age, 10 of 16 (62%) were benefited, of those from 21 to 45 years of age, 29 of 73 (40%) were benefited, and of those over 45 years of age (all with nodular goiter) 11 of 22 (50%) were benefited.

In Robertson's opinion the contraindications to thiouracil treatment are (1) signs of pressure on the airway, since enlargement of the goiter is common during the first few weeks of treatment, (2) toxic nodular goiter or a retrolaryngeal upper pole of the thyroid gland, since patients with these conditions continue to complain of discomfort in the neck despite an improved basal metabolic rate, (3) pronounced exophthalmos, (4) predominance of heart symptoms, e.g., tachycardia and fibrillation, as these are the last symptoms to disappear with thiouracil treatment as opposed to their early disappearance following surgery, (5) depression due to thyrotoxicosis, since, like the sulfonamides, the thio compounds are inclined to cause depression in some patients, and (6) absence of facilities for frequent blood counts.

Indications for the use of thiouracil are (1) the youth of the patient, (2) predominance of nervous symptoms other than depression, (3) elderly patients who are grave surgical risks, (4) recurrent thyrotoxicosis after operation, and (5) severe thyrotoxicosis requiring preparation for operation.

Subtotal thyroidectomy was carried out in more than 250 patients including all those who failed to respond sufficiently to thiouracil. Of those aged under 21 years, 14 of 16 responded well, of those between 21 and 45 years of age, all responded well, and of those aged over 45 years, with the exception of 1 who died, all responded satisfactorily.

WAYNE FIELD CAMERON M D

Cancer of the Larynx CHEVALIER L JACKSON, JOHN V BLADY, CHARLES M NORRIS, and WALTER H MALONEY *J Am M Ass*, 1948, 138 1080

Six-hundred and twelve patients with cancer of the larynx were treated at the Temple University Hospital, Philadelphia, from 1930 to 1947, inclusive. Two-hundred and nine were treated by laryngofissure, 244 by laryngectomy, and 159 by irradiation. The criteria for the selection of treatment are not stated, but no patient having cervical metastases when first seen had operative treatment.

The primary 5 year cure rate among 206 traced patients with carcinoma of the larynx without metastases when first seen was 68 per cent. An additional 7 per cent revealed 5 year cures following retreatment of recurrence or metastases, which made a total 5 year curability of cancer of the larynx without metastases when first treated of 75 per cent.

wheel at the inferior temporal margin of the orbit, with the use of a 22 gauge needle, 3.5 centimeters long. The anatomic arrangement of the muscle cone is such that an anesthetic is retained and affects the nasal ciliary nerve, the long and short ciliary nerves, the ciliary ganglion, the optic nerve, and the third and fourth nerves. Epinephrine injected retrobulbally in the procaine results in a decrease in the intraocular pressure. The injection is indicated prior to all intraocular operations, muscle operations, eviscerations, enucleations, and in cases of acute glaucoma for the immediate relief of pain.

Anesthesia for operations on the lacrimal sac may be obtained by blocking the anterior ethmoidal and infratrochlear nerves at the superior margin of the orbit nasal to the trochlea. The infraorbital nerve may be blocked at either the infraorbital canal or fissure.

Field block of the lids is obtained by injection of procaine close to the periosteum near the orbital margins.

FRANK W NEWELL, M D

EAR

Test Findings Before and After Fenestration of the Labyrinth EDWARD H CAMPBELL and DOUGLAS MACFARLAN *Arch Otolaryngol*, Chic., 1948, 47 590

A careful evaluation of hearing is important in considering candidates for the fenestration operation. Most important is the determination of the degree of conduction loss and, if present, the degree of perceptive deafness. Audiometer and tuning fork tests of air and bone conduction are necessary. The fatigue test should be done in one or two frequencies in the speech hearing zone. Fatigue appears in all types of nerve deafness but not catarrhal deafness or early otosclerosis. A carefully performed Gelle test, if negative, is evidence against stapes fixation. Matching of the loudnesses in the two ears (loudness balance test or recruitment) by raising the intensity does not occur in the stage of otosclerosis considered operable.

In cases of nerve or mixed deafness, recruitment may be demonstrated for those frequencies showing nerve degeneration. Speech hearing tests have indicated that patients with conductive deafness showed continuously better hearing as loudness was increased, whereas with nerve deafness a level of loudness was reached at which there was an end of the patient's maximum efficiency in speech discrimination (Walsh and Silverman). Caloric and tuning tests aid in evaluating functional activity of the inner ear mechanism.

In their fenestrated patients, the authors noted that nystagmus following operation was almost always to the opposite side. The active postoperative fistula response was usually associated with the best hearing result, however, this was not always true. A study of the hearing for speech and for pure tones following the fenestration operation did not permit any definite correlation between the two.

JOHN R LINDSAY, M D

	Patients traced	5 year cure rate
Laryngofissure	102	81%
Laryngectomy	35	66%
Irradiation	69	51%
Total	206	68%

The curability of recurrences is as follows

Original treatment	Patients re-treated and traced 5 years	5 year cures	5 year cure rate after retreatment
Laryngofissure	16	7	44%
Laryngectomy	12	1	8.3%
Irradiation	20	7	35%
Total	48	15	7% of 206 cases

Recurrence, metastases, or both developed following treatment by laryngofissure in 19 per cent of the cases, following laryngectomy in 34 per cent, and following irradiation in 33 per cent. When there was recurrence or metastases following laryngofissure, it occurred within the first 3 years in 74 per cent, and after 5 years in 22 per cent (in these patients, 1 case each in the seventh, ninth, twelfth, and fifteenth years, respectively). Thus, following laryngofissure, the 5 year criterion of curability is but 78 per cent accurate. Among these cases, when recurrence or metastasis occurred following laryngectomy or irradiation, it occurred within 5 years.

Fourteen patients had metastases when first seen. All were treated with roentgen irradiation. None survived 5 years.

Thirty-three patients had metastases after receiving treatment for the primary lesion. Of these, 29 received treatment for the metastases. Seven survived 5 years, a 5 year survival rate of 21 per cent. Methods of treatment of the metastases which developed following treatment of the primary lesion, and results of treatment are shown

	survival	5 year cure rate
X rays	13	1
X rays and radon	3	1
Radon alone	4	0
Surgery x rays radon	9	5
No treatment	4	0
Total	33	7

Of the methods employed, surgery combined with irradiation gives the best 5 year results in cervical metastases—a 5 year curability of 55 per cent.

From these figures it would appear that laryngofissure, with an initial cure rate of 81 per cent and a salvage rate of 44 per cent of recurrences, is the treatment of choice whenever possible. However, it is strongly urged that its use be severely restricted to suitable cases.

Since 1940, the treatment of cervical metastases from cancer of the larynx at the Temple University Hospital has been as follows:

For patients presenting metastases on admission, roentgen treatment is generally employed for treatment of the primary lesion in the larynx, if possible, the metastases are incorporated in the same portal. After the irradiation, either before severe irradiation epithelitis develops or after it has completely healed, the metastases are surgically exposed and radon is implanted in a tissue dosage of from 5,000 to 10,000 gamma roentgens, or a neck dissection with or without the implantation of radon is performed.

More recently, some patients have been treated by radical neck dissection followed by external irradiation to the primary lesion. In a few cases laryngectomy combined with neck dissection has been done. The results in these cases, however, are not suitable for evaluation, because the treatment was given less than 5 years ago.

For metastases occurring after the primary disease has been controlled, a radical neck dissection is performed, and radon is implanted when there is perinodal infiltration.

FRANK B. QUEEN, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS, CRANIAL NERVES

Purulent Pachymeningitis SIR HUGH CAIRNS and F SCHILLER. *Proc R Soc M, Lond*, 1948, 41 805

The authors draw a line of distinction between purulent pachymeningitis and subdural abscess in that the former consists of a film of pus of variable thickness lying in the subdural space and not circumscribed, whereas the subdural abscess is considered as a purely loculated collection of pus in the subdural space (This distinction is probably comparable to our terminology of acute and chronic subdural abscess—abstractor's note)

This series of 33 cases had been collected over a 20 year period so it allowed a correlation of the effects of the antibiotics and sulfonamides in the treatment of this condition. In 23 of the cases the primary infection was in the paranasal sinuses, in 6 cases it was in the petrous bone, and in 4 cases the infection was from a distant focus. A spreading osteomyelitis of the skull was present in 26 of the cases. The use of antibiotics may greatly alter an osteomyelitis of the skull, hence, it is possible that a very mild involvement may have been overlooked in some cases. Thrombosis of the large dural sinuses or cerebral veins was present in 8 cases. Although leptomeningitis was a common sequela before the days of penicillin, this condition is becoming comparatively uncommon.

It is felt that the clinical picture of purulent pachymeningitis is so sharply defined that the diagnosis should not be difficult, however, it is thought to bear some resemblance to uncomplicated cerebral thrombophlebitis. In case of doubt, there should be no hesitation in trephining and in opening the dura. There are usually only a few cells in the cerebrospinal fluid and comparatively little nuchal rigidity unless the condition becomes complicated by leptomeningitis. The symptoms are usually those found in infection of the central nervous system, followed rapidly by hemiplegia, homonymous hemianopia, sensory disturbances, and occasionally convulsions in the early stages.

The most common organisms were anaerobic streptococci, viridans, or other nonhemolytic forms. Staphylococcus and Betahemolytic streptococcus were rare. Formerly this infection was almost invariably fatal, however, since the advent of penicillin the prognosis has been greatly improved. Fifteen of the patients in this series were treated to a variable extent with penicillin. Five patients, who were incompletely treated because of an insufficient supply of penicillin, expired. Of the 10 patients who were adequately treated, 7 recovered. The preferred method of treatment is to place rubber catheters through a burr hole into the subdural space and, at frequent intervals, to instill large quantities of dilute

penicillin—approximately 6 c.c. of a solution containing 500 units per cubic centimeter. In addition the patient is usually given intramuscular doses of 100,000 units every 3 hours unless in vitro sensitivity tests reveal that the organism responds readily, after which the dosage may be cut in half. It is believed that the solution injected in the subdural space is absorbed, since very little of it drains back through the catheter. Instillation of penicillin in the subdural space also tends to prevent loculation or typical subdural abscess. However, in 8 of the 10 fully treated patients loculated subdural abscesses developed and in 2, intracerebral abscesses. The possibility of the late onset of a loculated subdural abscess must always be suspected in cases in which there is either a failure of definite recovery, or in which there is a slight retrogression. In such cases it is necessary to perform ventriculography to rule out a loculation on the medial surface of the hemisphere, or an intracerebral abscess. Although gross osteomyelitic involvement of the skull should be removed surgically, the massive removals that were formerly practiced will probably not be necessary when full doses of systemic penicillin is used.

If the primary focus persists after the patient has recovered, this should be dealt with radically, however, it may be deferred for some months. It is suggested that since so many of the cases of purulent pachymeningitis follow operative procedures upon the paranasal sinuses, such operations should be accompanied by prophylactic doses of penicillin both before and after surgery. JACK I. WOOLF, M.D.

Modern Surgical Treatment of Acute Subdural Abscesses E. S. GURDJIAN and JOHN E. WEBSTER. *Arch Surg*, 1948, 57 411

The authors report a study of 4 consecutive cases of acute subdural abscess in patients who were successfully treated by operation and penicillin. They attribute the excellent results obtained in these cases to the use of antibiotics and sulfonamides since the surgical management has remained essentially unchanged. This article includes an excellent historical review dating back to the first successful operation of subdural abscess by de la Peyronie, in 1699.

The mode of infection may be by direct extension from the mastoid or paranasal sinuses, or following neglected compound fractures of the skull. An indirect mode from the sinuses may occur by retrograde thrombophlebitis and perivascularitis. The primary source of infections in the 4 cases in this report were a chronic sinusitis in 2 patients and an acute sinusitis in 2. One must always be aware of the possibility of an associated osteomyelitis (1 case) and particularly of an intracerebral abscess (2 cases). Although the exudate is usually over the convex surface of the brain, it may be loculated between the medial surface of the hemisphere and the falx.

A subdural abscess should be considered in any patient with mastoiditis or a paranasal sinus infection who develops severe headaches, drowsiness, convulsive seizures, and increased intracranial pressure. It should be remembered that these symptoms may develop in from 2 to 5 days from the onset of the intracranial spread of infection. All of the 4 patients comprising this report had convulsive seizures—both Jacksonian and generalized in type. Hemiparesis, aphasia, and other focal signs are commonly present. The presence of meningitis should not hinder one in attacking the lesion surgically. Although there may be an associated intracerebral abscess, this usually runs a more protracted course and should be suspected particularly in those patients who either fail to show definite improvement within a few days after treatment or who show a progression of symptoms.

Treatment consists of the insertion of burr holes or simple trephination of the skull and washing out of the subdural space with saline or penicillin, and inserting soft rubber catheter drains into the subdural space. Although no pus was seen to drain from the catheters, they served as a means of introducing penicillin solution into the subdural space. The instillation of penicillin into the subdural space is carried out for a period of 3 days. Systemic penicillin was also given in doses varying from 20,000 to 100,000 units every 3 hours. If improvement is not rapid, further exploration is indicated. The importance of attacking surgically the original focus of infection is emphasized. This should be done at the time of the intracranial procedure, or preceding it.

The most important sequela is the presence of convulsive seizures. Three of the 4 patients in this series continued to have convulsive seizures after recovery, although 2 of them were well controlled with anticonvulsive medication. Although this is probably due to the scarring between the cortex and the arachnoid, it is interesting that in 2 cases requiring operation at a later date for an intracerebral abscess, inspection of the arachnoid failed to reveal any macroscopic evidence of cicatrization.

JACK I. WOOLF, M.D.

Late Complications Following Cranioplasty with Alloplastic Plates JAMES C. WHITE *Ann Surg*, 1948, 128: 743

This article is based on answers to a questionnaire, in which case reports were obtained on 151 late complications following the insertion of plates of tantalum, vitallium, and acrylic resin, which came into standard use in our military hospitals during the War.

A brief review is given of the history and development of cranioplasty. From this study of 151 reports of late complications, the author states that definite conclusions regarding the use of plates in the repair of cranial defects can be made. Late complications have occurred most frequently after plating of the frontal bone, especially in reconstructions of the orbital ridge. To construct and secure in place a perfectly fitting plate in this area is a difficult technical

feat. In addition, this region is particularly susceptible to trauma and infection from the frontal sinus and nasal cavity. Complications from these sources are likely to occur as long as the patient lives. It is the author's feeling that the use of autogenous bone for repair of the orbital ridge is probably preferable to the use of metallic plates. However, he suggests the continued use of metallic plates for covering extensive defects in the frontal bone above the level of the sinus.

When swelling and tenderness have developed after an apparently successful plating, treatment by aspiration and penicillin have occasionally been followed by subsidence of the infection when the organism has been sensitive to penicillin and there has been no other predisposing factor such as slipping of the plate, inadequate circulation of the scalp, or communication with the frontal sinus. In the presence of a granulating sinus with exposure of the underlying plate, it is usually best to sacrifice the plate without delay, although in 26 cases of this series chemotherapy and plastic procedures were followed by ultimate healing. The author suggests the immediate removal of any plate which is grossly infected or has loose bone or metallic fragments underlying it, to avoid the risk of infection of the dura with serious risk to the patient and unnecessarily prolonged hospitalization.

Two deaths are reported following the insertion of metallic plates in the stage of active infection, but no other fatal complications have been reported.

In regard to the choice of material in alloplastic plates, the author states that tantalum, vitallium, and acrylic resin give rise to complications of the same order and frequency. Tantalum is by far the easiest to process and fit at the time of operation. The insertion of metallic plates should be postponed for a long period in subjects who are likely to develop epilepsy. This complication, of course, occurs most frequently after deep wounds with dural penetration, indriven bony spicules or metallic fragments, and added sepsis. It would seem wise under these circumstances to wait at least a year and then to use plates of acrylic resin which are visible in roentgenograms, if there has been any history of seizures or evidence of an epileptogenic focus in the electroencephalogram.

It appears advisable not to attempt a primary repair after craniocerebral trauma, but to wait for at least 2 months if the wound heals by first intention. If there has been initial infection, plating should be deferred for at least 6 months, and longer in cases of infection with penicillin-resistant bacteria.

The most common complication after cranioplasty is infection or necrosis of the overlying scalp. The causes of failure after plating and the precautions necessary to prevent it are discussed in this article. The facts disclosed appear to justify the conclusion that a safe, simple, and satisfactory repair of a large cranial defect can be accomplished better and with no greater risk with an alloplastic plate than with grafts of cartilage or bone. When the

cranial defect involves the frontal sinus, however, a return to the use of grafts of living bone is recommended

HOWARD H. LANDER, M D

Glossopharyngeal Neuralgia (Sulla nevralgia del glossofaringeo) M CRISTIANI *Minerva med*, Tor, 1948, 39 659

Glossopharyngeal neuralgia is a very rare condition which creates a characteristic clinical picture. Those not familiar with it may mistake the disease for a neuralgia of the trigeminal nerve. The syndrome may create diagnostic difficulties if it is accompanied by earache, pain in the region of the eye, the angle of the mandible, or the neck. Anastomosis of the ninth nerve with the sphenopalatine ganglion, optic ganglion, or the second and third branches of the fifth nerve are responsible for such complications.

The author's patient, a man 56 years of age, suddenly developed severe pain in the region of the right tonsil, radiating toward the base of the tongue and the pharynx. The pain was aggravated by deglutition. Application of a 5 per cent cocaine solution to the trigger zone in the right tonsil provided temporary relief.

No local lesion could be detected. The neurologic examination failed to reveal any involvement of other cranial nerves. Administration of large doses (50 mgm) of vitamin B₁ daily for 7 days, followed by smaller doses for 2 more weeks, produced a complete disappearance of the painful attacks. A check-up 6 months later showed the patient to be in perfect health. A more prolonged observation is required before a statement of a complete cure can be made.

Neuralgia of the glossopharyngeal nerve usually does not yield easily to conservative therapy, consisting of the administration of various drugs, diathermy, etc. Alcohol injections are contraindicated because of the proximity of the vagus, hypoglossus, and sympathetic nerves and large blood vessels. The employment of large doses of vitamin B₁ seems, therefore, to be a valuable addition to our armamentarium.

JOSEPH K. NARAT, M D

SPINAL CORD AND ITS COVERINGS

The Effect of Injury to the Spinal Cord and Cauda Equina on the Sexual Potency of Men DONALD MUNRO, HERBERT W. HORNE, JR., and DAVID P. PAULL *N. England J. M.*, 1948, 239 903

The various aspects of sexual function in patients with spinal cord injuries has received comparatively slight definitive study. Most of the knowledge in this regard has been derived from earlier physiologic studies on animals. At Cushing Veterans Administration Hospital, 84 patients with variable injuries to the spinal cord were investigated in this regard. The cases were divided into two main groups:

1. Transections of the spinal cord, which were subdivided into those verified anatomically and

those in which a continuity of the cord was found at operation, the continuity may have been maintained by scar tissue or, if the cord had not been visualized, the character and length of the clinical course of the patient left no justifiable doubt as to the diagnosis of a transection.

2. Partial cord injuries, in which there was some preservation of cord function as evidenced either by retention of sensation or voluntary motion below the level of the injury.

The three main aspects of sexual function that were examined were in regard to erections, ejaculations, and the ability of the patient to impregnate. The occurrence of priapism was analyzed in a separate group of 320 injuries of the spinal cord and cauda equina. Although it was found that it did occur more frequently in cervical injuries, this could not be considered of diagnostic significance. Erections take place on a purely segmental-reflex basis. The reflex is initiated by tactile stimulation of the glans, the impulses traveling to the second, third, and fourth sacral segments by way of the internal pudic nerves. The efferent impulses leave these same segments by way of the parasympathetic nerves and result in dilatation of the arterioles of the penis and congestion of the corpora cavernosa and spongiosum. Erections were present in 74 per cent of the 84 patients comprising this series. A destruction of the sacral segment of the cord or of the cauda equina and the pelvic parasympathetic nerves will prevent their occurrence. Associated findings will be an autonomous bladder and absent anal reflex. Injuries of any other portion of the spinal cord, regardless of the extent or level of the injury, should not prevent erections.

Ejaculations were found to be present in only 7 per cent of the patients. The authors believe that there are two possible lesions that may affect ejaculations. Since the second phase or actual emission of the semen is effective through impulses traveling over the internal pudic nerve, a lesion involving the sacral segments or cauda equina will prevent ejaculation. It is believed that there is no "center" for ejaculation in the lumbar cord, however, an extensive destructive lesion between the sixth thoracic and third lumbar segments which is sufficiently severe to interrupt the sympathetic components may also prevent ejaculation. Two patients in this series were able to successfully impregnate their wives. In one patient there was a partial lesion at the fifth cervical segment, and in the other a complete lesion at the level of the sixth and seventh thoracic vertebrae. It is not known whether a spinal cord lesion of any type will affect the possibility of viable spermatozoa; nevertheless, it is felt that any neural activity which may take place must occur by way of the sympathetic nervous system. A more detailed study of this problem is to be presented in a later paper.

JACK I. WOOLF, M D

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Carcinoma of the Breast Results from Statistical Research JOHANNES CLEMMESSEN *Brit J Radiol*, 1948, 21 583

The author concludes from a statistical study that heredity plays some part in the etiology of breast cancer, the disposition to which is inherited together with a disposition to other types of cancer. There is also a tendency for several members of the same family to inherit breast cancer with localization to the same breast.

There can be no doubt that breast cancer is more frequent in the left than in the right breast. Janet Lane-Claypon's figures show a connection between breast cancer and injury, and they suggest also that injury is more frequent on the left than on the right side.

The climacterium should be subjected to further studies with regard to incidence of cancer of the breast, as there is a fall in the incidence curve in the age groups from 45 to 55 years.

EARL O. LATIMER, M.D.

Carcinoma of the Breast "Precancerous Conditions" of the Breast E. K. DAWSON *Brit J Radiol*, 1948, 21 590

The term "hyperplasia" in mammary tissue covers two types of cellular proliferation, adenosis and epitheliosis. Adenosis produces larger and more numerous lobules and is best seen in early pregnancy, it occurs not only as a physiological response during active reproductive life but also during the involutional changes of the climacteric period, when hormonal stimuli are being readjusted because of ovarian decline. It may, at this period, be generalized and possibly unnoticed, or it may be localized. The climacteric patients may give a mildly positive Aschheim-Zondek reaction. This adenosis, described as glandular or lobular mastitis in the older terminology, may be patchy, irregular, and very exaggerated. After nearly 20 years of study, with detailed examination of many hundreds of all types of benign and malignant breasts (many in whole breast sections), the author has found no evidence in human mammary tissue that adenosis leads to the development of carcinoma. That is to say, adenosis, as such, does not become adenocarcinoma and is, therefore, in the author's experience, not a precancerous condition. It gradually fades out, with fibrosis and hyalinization, in very rare cases, it may produce sarcoma, through the intermediate stages of adenoma, fibroadenoma, and fibroma.

The other type of proliferation is epitheliosis, a cellular activity which fills up the ducts and smaller lobular structures. When carcinoma develops, it can be traced, in all cases in the author's experience,

to cell proliferation of the intraductal type, which, at the time of examination, may form a lining, a solid filling, or papillary ingrowths. That is to say, epitheliosis becomes, if malignant, epithelioma, in the French use of this term. However, only a minority of breasts which show epitheliosis microscopically become carcinomatous, in the majority of cases, after a phase of intraductal proliferation which is more or less prolonged, the cells degenerate, with or without cyst formation. The noncystic cases are the more dangerous because, when malignant, they give little or no warning before extensive cancerous development and spread have occurred. In most cases, however, there is some cyst formation. A grossly cystic condition usually means a benign lesion, with extensive degeneration of "pale" or eosinophile cell type, forming the blue-dome cysts of Bloodgood's description.

The author has found no evidence that the blue-dome cyst becomes cancerous and, like adenosis, it may be dismissed as a precancerous lesion. However, another type of cyst is more ominous. We may call it the fatty cyst, as the degenerating cells within it form masses of colostrumlike fatty or foamy cells. This cyst may also become completely atrophic, although the apparently slow removal of the "irritating" fatty contents is associated with periductal fibrosis and later contraction and fixation of the cyst, which produces a very suspicious clinical picture. However, the outcome of this type of cyst is not always atrophy and quiescence. If fatty material remains for a prolonged period within the ducts it may lead to malignant cell formation and growth by its action on surviving, viable epithelial cells still lining the duct or cyst. The author's experience suggests that cancer development in the breast is associated only, if not always demonstrably, with the presence of fatty material in the mammary ducts, at any level, although its source is not necessarily restricted to epithelial cell degeneration.

To summarize, very briefly, the pathologic point adenosis as such does not lead to carcinoma, neither does the blue-dome cyst, the majority of fatty cysts also eventually become quiescent, but with the fatty cyst, and in ducts with fatty contents or fatty degeneration of proliferated epithelium with little dilatation, there is always the possibility of the formation of a progressive epitheliosis which may become definitely malignant.

EARL O. LATIMER, M.D.

Carcinoma of the Breast Prognosis in Carcinoma of the Breast R. W. SCARFF *Brit J Radiol*, 1948, 21 594

It was stressed that although grading was of importance in carcinoma of the breast, it is obvious that the stage of the disease is of much greater significance as far as the ultimate prognosis is concerned. This does not rule out the importance of

histological grading, because the presence of metastases depends to a considerable extent on the histological type of the growth, and it is more likely that growths of high malignancy will show a higher percentage of cases with secondary deposits in glands at the time of operation

In the breast a combination of histological grouping and clinical staging has produced results which, in the main, are satisfactory, although they have been disappointing to some extent

Clinicopathologic grading and staging of carcinoma of the breast give useful information for the prognosis in the cases that are treated by radical mastectomy, especially if the technique advocated by Handley and Thackray is adopted, i.e., simultaneous histological examination of the lymphatic glands from the internal mammary chain

EARL O LATIMER, M D

Carcinoma of the Breast Discussion on Carcinoma of the Breast SIR STANFORD CADE *Brit J Radiol*, 1948, 21 596

The author suggests the following grading of malignancies of the breast

Stage I Tumor of the breast only

Stage II Tumor of the breast plus skin changes, or axillary gland changes, or both

Stage III Tumor of the breast plus changes in the supraclavicular or contralateral axillary glands or fixation to the pectoral fascia

Stage IV Skeletal or visceral metastasis

The involvement in stages I and II is anatomically within the area covered by radical mastectomy, in stage III it is beyond surgical excision, and in stage IV it is suitable for palliative measures by radiation or endocrine therapy

The zone of demarcation between a good and bad prognosis, between a fair and poor chance of survival, is the clinical state of the axillary glands. It is, of course, agreed that sometimes clinically nonpalpable glands show histological invasion, and, conversely, palpable enlarged glands show, occasionally, inflammatory stages only, but on the whole the presence or absence of palpable and clinically malignant axillary glands is the best guide to the prognosis for the patient

It is the author's contention that in Stage I of the disease the best method of treatment is radical mastectomy. Postoperative irradiation in this group of cases as an additional measure is of doubtful value

It is important to draw attention to the limitation of usefulness of radical mastectomy. It gives the best results in Stage I. The results in Stage II are much worse, and by itself the operation offers a chance of 5 year survival in only about 20 to 30 per cent of the cases. Stage II should be analyzed. It includes enlarged axillary glands and skin invasion. There are three types of skin invasion

1 Direct spread and fungation, this is the least malignant type

2 Diffuse invasion with edema (the pigskin or *peau d'orange* type), this is of grave significance

3 Invasion of the skin by discrete nodules (so admirably described by Sampson Handley), this type is a death sentence

In such cases radiation is the weapon of choice and preoperative irradiation is, on common sense grounds and from clinical observation of cases and histological studies, the method of choice. Radium or the more flexible and equally suitable method of roentgen irradiation leads to regression of the disease and transforms a percentage of cases into Stage I cases, suitable for surgery, in other cases the progress of the disease is arrested and life is prolonged by many years

In Stage I cases postoperative irradiation gave a 5 year survival of 53 per cent and preoperative irradiation a 5 year survival of 73 per cent. The figures by E. Berven from the Radiumhemmet, Stockholm, are even more striking, with fixed axillary glands the 5 year survival with postoperative radiation was over 97 per cent, whereas with preoperative and postoperative treatment it rose to 32 per cent

The value of local mastectomy is clear-cut—it removes the breast and the primary tumor. It does not touch the axillary contents and if disease is present there—palpable or nonpalpable, operable or inoperable, actual or potential—there the disease remains. The author is not attracted by the idea of removing only part of a cancer, be it in the breast or elsewhere, if he can, with impunity to the patient, remove all of it. Simple mastectomy is suitable in the aged for the removal of a fungating mass, in bad surgical risks with localized disease, and in cases in which radiation is not available or suitable. Simple mastectomy has its value, it has also, like the radical operation, definite limitations. As a routine surgical procedure, regardless of the stage of the disease or the age of the patient, it is a retrograde step and is quite unwarrantable

EARL O LATIMER, M D

Carcinoma of the Breast The Value of Simple Mastectomy and Roentgen Therapy in the Treatment of Cancer of the Breast R McWHIRTER. *Brit J Radiol*, 1948, 21 599

The main method of treatment in the period from 1941 to 1945 was simple mastectomy and roentgen therapy. Full treatment was possible in almost all cases, but, whether fully treated or not, every case classified as operable has been included

At the Royal Infirmary of Edinburgh the 5 year survival rate was 62.1 per cent when simple mastectomy and postoperative radiation was used

During the period from 1935 to 1940 the main method of treatment was radical surgery and postoperative roentgen therapy, and of the 411 operable patients, 50.1 per cent were alive after 5 years

Statistical examination shows that this difference in the survival rates is significant, and the findings, so far as the 5 year survival rate is concerned, suggest that roentgen therapy is a better method of treatment of the axilla. The results obtained in the advanced cases without distant metastases support this observation

With regard to the survival rate of all advanced cases without distant metastases in the period from 1941 to 1945 the author states that treatment by simple mastectomy and roentgen therapy was possible in only a limited number of cases, but all cases, whether fully treated or not, and all untreated cases, are included. The cases in this group are essentially those in which the disease was too advanced to be treated by radical mastectomy, but was still to some extent localized, so far as could be ascertained by clinical and roentgenographic examination. The group, therefore, includes all cases in which the primary tumor was fixed to the pectoral muscle or to the underlying ribs, and all cases in which there were fixed axillary glands or glands in the supraclavicular region, 29 per cent of the patients were alive at the end of 5 years. This remarkably high figure clearly demonstrates that roentgen therapy is an effective method of treatment of the axilla even when the axillary involvement is gross.

The 5 year survival rate in all cases referred during the period from 1941 to 1945 was 43.7 per cent. It is interesting to compare this figure with that obtained during the period from 1935 to 1940, when the main method of treatment was radical mastectomy and postoperative roentgen therapy. There were 790 cases referred during this earlier period and the 5 year survival rate was 32.4 per cent.

The following is a brief summary of the essential points of the technique of simple mastectomy and roentgen therapy.

The method of treatment is a combination of two procedures which must be coordinated if the best result is to be obtained.

The following points are of importance in the surgical aspect of treatment.

1 Preoperative preparation with iodine is contraindicated because it lowers the skin tolerance to roentgen therapy.

2 The skin incision and the undermining of the skin flaps should be as limited as possible so that tissue spaces outside the area to be irradiated will not be contaminated with malignant cells liberated during the operation.

3 Excessive skin should not be removed for tension on the skin flaps may be associated with failure of the wound to heal and delay in the application of roentgen therapy. Tightly stretched skin flaps do not tolerate irradiation well. Skin grafting does not overcome the difficulty, for grafts do not tolerate x-ray treatment well.

4 When the primary tumor is mobile on the pectoral fascia, the fascia should not be removed, as this promotes fibrosis of the pectoral muscle. If the tumor is firmly fixed to the pectoralis major, the muscle should be removed together with the breast.

5 If there are no palpable axillary glands dissection should not be performed, but superficial mobile glands in the subpectoral region and outside of the axillary fascia may be removed. Any further dissection of the axilla will defeat the whole purpose of the treatment method advocated.

6 If the patient is very stout it is better to carry out a radical mastectomy, because in stout patients it is difficult to deliver an adequate dose of x-rays to the axilla.

7 Supraclavicular glands should never be removed, because these glands are easily and effectively dealt with by roentgen therapy.

8 Adhesive should not be applied to the skin after the operation, because this lowers the tolerance of the skin to irradiation.

The following points are of importance in post-operative treatment by roentgen therapy.

1 Only one full course of x-ray treatment should be given. The practice of giving repeated courses at intervals of 3 to 6 months has no place in the treatment of any form of malignant disease when cure is to be attempted, and is just as illogical as partial removal of a tumor at intervals of 3 to 6 months.

2 X-ray treatment should be commenced as soon as possible after the operation, the usual interval is 2 weeks.

3 Four fields are used and every field is treated every day. The axilla is irradiated from two opposed fields and the anterior field extends up to include the supraclavicular region. The chest wall must be treated from tangential or glancing fields so as to avoid lung fibrosis.

4 An adequate dosage must be given, and in Edinburgh the patients receive a minimal tumor dose of 3,750 roentgens in a period of 3 weeks. This is the same dosage as is given when clinically obvious local recurrences are treated, and it is important not to give less.

5 The x-ray apparatus must be sufficiently powerful to deliver an adequate depth dose in the axilla and it is doubtful if effective roentgen therapy can be given with an apparatus of lower voltage than 250 kv. Heavy filtration is employed and the half-value layer of the beam is 3.7 mm. of copper.

EARL O. LATIMER, M.D.

Carcinoma of the Breast The Surgical Aspect of Carcinoma of the Breast R. C. B. LEDLIE *Brit J Radiol*, 1948, 21: 610

The author classifies cancer of the breast as follows:

Stage I The growth is confined to the breast, involvement of the skin directly over and in continuity with the tumor is not considered, provided that the area involved is small in relation to the size of the breast.

Stage II The growth is similar to that in Stage I, but there are palpable mobile nodes in the axilla.

Stage III The growth extends beyond the corpus mammae as (1) the skin is invaded or fixed over an area large in relation to the size of the breast, or it is ulcerated, and (2) the tumor is fixed to the underlying muscle or fascia. Axillary nodes may or may not be palpable, but if nodes are present they must be mobile.

Stage IV The growth extends beyond the breast area as shown by (1) fixation or matting of the axil-

lary nodes, (2) complete fixation of the tumor to the chest wall, (3) metastases in the supraclavicular nodes, (4) metastases in the skin wide of the tumor (5) metastases in the opposite breast, and (6) distant metastases, e g, in the bones, liver, and lungs

In practically all Stage I cases, and in a small percentage of Stage II cases (in which one isolated mobile axillary node low down was enlarged and indurated), the author advises radical amputation, unless it is contraindicated by the patient's poor general condition or extreme age, or in cases of pregnancy or lactation, on the assumption that surgery holds out the best hope of eradicating the disease. This has been the author's policy throughout the entire period from 1937 to 1946, and he has found no reason to alter his attitude up to date.

During the first 7 years of the period under review the author advised initial radical amputation in a great majority of Stage II cases and also in a limited number of Stage III cases.

In all cases in which it was available he relied on the pathologist's detailed report on the tissues removed by radical amputation in deciding whether postoperative x-ray therapy was needed. The pathologist's prediction was based on a summary of a number of features, including the size and situation of the primary tumor, its histological type, its relation to or involvement of the overlying dermis, the number of lymphatic channels invaded, and whether the invasion was widespread or limited to a few isolated cells. Perilymphatic infiltration and invasion of blood vessels or nerves were noted, as was the involvement of muscle or fat. Lastly, the number and position of any affected axillary lymph nodes and the extent of their involvement, as well as any perinodal spread, were correlated with the findings in the breast. Postoperative x-ray therapy was given in all cases in which the pathologist predicted that the outlook was indefinite or bad.

Throughout the 10 years under review, x-ray therapy was employed as the initial treatment in (1) the majority of Stage III cases, (2) nearly all Stage IV cases, (3) a small group of cases comprising carcinoma occurring in pregnancy or lactation, mastitis carcinomatosa, and (4) a limited number of Stage I and Stage II cases, occurring in aged and decrepit patients.

Postoperative roentgen therapy following radical amputation has resulted in a marked increase in the symptom-free rate in cases with axillary node involvement. This improvement in results has been seen in both 3 year and 5 year survivals.

X-ray therapy when used (in some Stage II cases, and chiefly Stage III and IV cases) alone produced a regression of the disease in the treated area in a large majority of cases, but distant metastases were responsible for death in most of these (79 per cent) within 3 years. In all of the patients who survived for a longer period (21 per cent) the disease had recurred by the seventh year.

During the period from 1944 to 1946 initial x-ray therapy was employed in an increasing number of

Stage II cases in which more than one axillary node appeared to be invaded. Previous experience with these cases had shown that radical excision and postoperative x-ray therapy usually succeeded in controlling the disease in the treated area, but, in spite of this fact, distant metastases at a later date led to an unfavorable result in an appreciable number. After the initial course of x-ray therapy was completed in a period of about 4 or 5 weeks, the patient was kept under regular observation at intervals of 1 to 2 months. As long as the disease appeared to be regressing in both the breast and the axilla the author refrained from surgery. However, radical amputation has been the treatment of election and has usually been performed at an interval of from 2 to 6 months after x-ray therapy has been completed. The skin sutures are left *in situ* for from 14 to 18 days, as on one occasion when this was not done the flaps separated and secondary suture was necessary.

Amputation of the breast alone or wide local excision of the residual tumor has been reserved for (1) those aged or decrepit patients who were considered unfit for a major procedure and (2) advanced cases in which the initial regression of the primary tumor in the breast was slight, or in which the breast tumor after a period of regression, commenced to enlarge again.

EARL O LATIMER, M.D.

TRACHEA, LUNGS, AND PLEURA

Decortication of the Nonexpandable Postpneumothorax Tuberculous Lung. DANIEL A. MULVIHILL and ROBERT KLOPSTOCK. *J Thorac Surg*, 1948, 17: 723.

In about 5 per cent of cases of pulmonary tuberculosis, in which a successful pneumothorax has been maintained for the optimal time, the lung will not re-expand after pneumothorax refills have been abandoned. The inability of the lung to re-expand usually results in highly negative intrapleural pressures, due to absorption of some of the pneumothorax air, and the drawing toward the chest wall of the collapsed lung together with the mediastinum and its structures. The opposite lung may therefore become overdistended, and latent foci may be opened.

The causes of the failure of the collapsed lung to re-expand are (1) extensive destruction and fibrous contraction of a greater part of the lung, (2) a rigid, thick visceral pleura, which is often the result of a pleural effusion or empyema, and (3) a stenosis of the large bronchi, with resultant atelectasis. The first and third causes still call for thoracoplasty as the method of treatment.

The pathology of the rigid visceral pleura—the second cause for failure of re-expansion—is not always inflammatory thickening of the pleura itself. Not uncommonly, it consists of the laying down of a hyalinized fibrous layer on the pleura, to which it is not intimately adherent in large part but is attached by a thin areolar, vascularized layer, which may be easily separated by blunt dissection to leave behind an intact and fairly normal and expandable pleura.

In the light of this described pathology, the feasibility of decortication in some cases in which expansion does not take place is clear, and has been proved in the 5 cases reported

The following list of possible indications has been tentatively set up

1 To increase functional respiratory capacity, when it is required to permit major collapsing procedures, or resection for an open lesion on the contralateral side

2 To avoid extensive thoracoplasty for the obliteration of the pleural dead space (a) when pleural effusion is persistent or recurrent on attempted re-expansion, (b) when a secondary pyogenic non-tuberculous empyema is present, and (c) when attempted re-expansion results in the shifting of the heart and mediastinum toward the chest wall, creating overdilatation dangerous to the opposite side

3 Nonexpandability in the face of the patient's desire to abandon pneumothorax, and avoid indefinite refills

Only long time observation of a long series of cases can determine the percentage expectancy of reactivation of the old tuberculous focus, or reopening of the cavity, after decortication, as compared with the more controlled re-expansion in readily re-expandable lungs on abandonment of pneumothorax

Detailed case histories of 5 patients who have had surgical decortication for postpneumothorax non-expandable lungs are presented. Pulmonary decortication seems to be a useful procedure for dealing with the problem of the postpneumothorax, nonexpandable lung

SAMUEL KAHN, M D

The Use of Streptomycin in Resection for Pulmonary Tuberculosis DWIGHT E HARKEN, JOHN J CINCOTTI, and GEORGE G JACKSON *Surg Clin N America*, 1948, 28 1519

The authors believe that extirpative therapy gives better results than collapse therapy in patients with pulmonary tuberculosis. Some previous results have been discouraging, however, technical refinements and antibiotic and chemotherapeutic advances support this method of treatment. Favour and his associates assume that streptomycin is effective only against extracellular organisms, and this assumption is supported clinically by the good results which have been obtained with its use in exudative diseases, fresh military lesions, and hyperemic nonfibrous lesions

Nine cases are presented in which resection was done for pulmonary tuberculosis. Indications for resection were tuberculoma, symptomatic tuberculous bronchiectasis, collapse failure, bronchial stenosis, secondary suppuration, giant cavitation, and a suspected neoplasm. Streptomycin was given 1 week previous to operation and was continued for 2 weeks after operation. The dosage varied from 1 to 2 gm daily, given at intervals of 4 to 12 hours. One gram of streptomycin and 100,000 units of penicillin were instilled into the pleural space at operation, and the

instillation was continued in cases of pleural contamination. Eight of the 9 patients were clinically well and had negative sputum, none had tuberculous spread, empyema, fistula, or wound infection. One fatality occurred in a desperately ill patient whose nonsurgical prognosis was hopeless

The article includes a report of 10 cases, in one of which pneumonectomy was performed for cancer associated with tuberculosis. In this series treatment extended over a period of 14 months, and it is believed that the material and time element are too limited for definite conclusions. In these cases streptomycin was used as a means of prevention of pleural and wound contamination—not as a cure

In the preparation of patients for operation, the use of streptomycin must be judicious because of streptomycin-resistant strains of the tubercle bacillus. Resistance may be from accommodation of the bacillus to streptomycin, or from proliferation of resistant strains. This factor is thought to begin in about 35 days. The effective dose of streptomycin has not been established. In considering the effectiveness of streptomycin as a means of control of wound and pleural infections, one must remember that aseptic technique is the most important factor

The authors state that thoracoplasty is safer after resection than it is as a primary procedure because the disease has been removed. It is pointed out that the use of streptomycin may prove to be of advantage in the conservation of useful parenchyma by segmental resection, and that streptomycin may inhibit the reactivation of quiescent pulmonary tuberculosis in unresected areas during and immediately following operation

ROBERT E FLORER, M D

The Use of Streptomycin in Pulmonary Resections JULIAN A MOORE, JAMES D MURPHY, and PARKER D ELROD *Surg Clin N America*, 1948, 28 1543

This article is a study of 63 patients who had undergone either lobectomy or pneumonectomy for pulmonary tuberculosis and had received streptomycin also. At first the dosage was 2 gm daily, given intramuscularly. Later it was changed to 1 gm daily, divided into two doses given at 12 hour intervals. Improvement in technique, equipment, and anesthesia has been of distinct advantage in recent years. The indications for pulmonary resection in this series were a residual cavity after thoracoplasty (45 per cent), destruction of the lung (12 per cent), failure of so-called conservative methods of collapse (15 per cent), tuberculoma (1 case), severe endo-bronchial disease and bronchiectasis (19 per cent), and elective operations in place of thoracoplasty in unilobar cavitation (8 per cent). All operations were done in the Overholt prone position. The intercostal nerves in the operative area were crushed near the midline to diminish postoperative pain. The bronchus was closed with interrupted silk sutures proximal to the point of clamping. Catheter drainage of the pleural space was used. Six weeks after resection a limited thoracoplasty was performed, the first rib being left in place

The over-all sputum conversion rate was 90 per cent. The mortality rate was 5 per cent, all deaths having occurred within 2 weeks after surgery. Two deaths were due to uncontrollable hemorrhage and 1 death was due to cerebral anoxia from cardiac arrest due to the hemorrhage at the operation. The surviving patients were in excellent clinical condition. Empyema developed in 4 cases as the result of bronchopleural fistula. No empyema developed when a tuberculous cavity was torn. Only one spread occurred, and this was not severe. There were 2 deep wound infections, both following thoracoplasties done 6 weeks after resection. Other complications were 1 case of meningitis, 1 of pericarditis, and progression of the disease in 1 patient. The patient with meningitis was treated with streptomycin and was apparently well at the time of writing. The patient with pericarditis survived, and the patient with progression is under treatment. Comparison is made with the cases reported in the literature prior to the use of streptomycin, and this reported series shows a marked improvement in the results.

ROBERT E. FLORES, M.D.

HEART AND PERICARDIUM

Decortication of the Heart in Fibrous Pericarditis
(La decorticazione del cuore nella pericardite fibrosa) LUIGI TORRACA *Gior ital chir*, 1948, 4 411

The author prefers the term fibrous pericarditis for the chronic malady which causes progressive thickening of the pericardium. He agrees with many students of this condition that most of the cases operated on are tubercular or rheumatic in origin, even though White does not admit rheumatism as one of the causes of this malady. Fibrous pericarditis may follow acute purulent pericarditis due to the *Staphylococcus aureus*. The author mentions 1 of his cases which followed a peritonsillar abscess, and 3 cases which followed a febrile attack with concomitant joint pains, which could have been considered attacks of acute arthritis. In many cases, however, the etiological factor remains obscure.

The rationale of surgical intervention depends on the fact that the symptoms which make up the clinical picture of fibrous pericarditis are due solely to the changes in the pericardium.

The former belief that pericardial changes hinder the cardiac systole has at present been superseded by that of Volhard, namely, that the fibrous tissue hinders the diastole and inhibits the full dilatation of the cardiac chambers. This is more marked in the right side of the heart. The diminished capacity of the right atrium and ventricle causes stasis in the venae cavae which leads to

1 Increased venous pressure (from 300 to 390 mm, the normal being from 50 to 100 mm.)

2 Turgidity of the superficial and deep veins, including the retinal veins

3 Hepatomegaly and ascites.

4 Dyspnea

5 Increased pressure of the spinal fluid (up to 400 mm H₂O)

6 Edema of the lower extremities

Because of the diminished capacity of the right side of the heart, less blood reaches the left side and consequently there will be less cardiac output, lower arterial pressure, tachycardia, and a weak pulse.

The author, however, does not agree fully with this conception of Volhard because

1 In 1 of his cases the roentgenogram revealed complete dilatation of the auricles and their impression on the esophagus. This dilatation became smaller 1 month after surgical intervention and the auricular impression on the esophagus almost disappeared.

2 Edema of the lower extremities should appear concomitantly with the liver congestion and ascites, but this is not the case.

3 Good results have been obtained with decortication of only part of the anterior surface of the left ventricle.

In this disease the size of the heart is not always small as stated by Volhard because in numerous cases the author found it to be enlarged on the surgical or on the autopsy table. This can be explained by previous enlargement due to some valvular lesion that was present before the fibrous pericarditis supervened. Whenever there is a concomitant valvular lesion, the heart tones are clear, but weak and distant, murmurs are present, and the pulse is weak and more rapid than normal.

Electrocardiography does not give any information of importance.

Roentgenography usually shows enlargement of the cardiac shadow. In 1 of the author's cases there was an increase in the transverse diameter of the heart, while in another case the enlargement was anteroposterior and included the auricles. This proves that the statement that the cardiac shadow is small in fibrous pericarditis, is not always true. Roentgenographic studies reveal also

1 Diminution of the movements of the cardiac borders, especially the right border.

2 No change in the shape of the heart when the patient is in lateral decubitus.

3 Pulmonary stasis (very evident in the author's cases).

4 Straightening of the heart borders which is due, according to Schmieden and Fisher, to increased diaphragmatic traction.

The author agrees with Westerman that in constrictive pericarditis surgical intervention is never too early, and disagrees with Vaguez and Santy, the former stating that surgical intervention must be considered only when cardiokinetics have no more effect on the heart, and the latter stating that there is plenty of time to intervene surgically as the course of the disease is very slow. The author refutes Sellor's statement that in constrictive pericarditis the cardiac muscle is normal, stating that as the pericardium begins to thicken, the connective tissue invades the myocardium and may reach the endo-

cardium (Burwell and Strayton) and the papillary muscles (Schmieden). He also adds the following as indications for early surgical intervention:

1 Increased work (pulsation) imposed on the heart muscle

2 The deleterious action of the progressive ischemia of the disease which will involve the coronary arteries and lead to atrophy of the heart muscle

The type of operation preferred by the author is the pericardiectomy of Rehn or the decortication of the heart of Sauerbruch and Schmieden. By the first term is meant removal of the fibrous pericardial sac and parietal serous lining, and by the latter term, removal of the epicardium in addition to removal as in the first term. Precordial thoracotomy can be done in some cases as a first step, to be followed later by pericardiectomy. The use of digitalis, because of its action to decrease the cardiac output, seems to be contraindicated. In support of this view the author mentions the case reported by Churchill in which, notwithstanding digitalization, the patient developed acute dilatation of the heart. Access to the heart has been through the mediastinum with resection of the third, fourth, and fifth, or third, fourth, fifth, and sixth costal cartilages, a portion of the sternum, and subperiosteal resection of segments of the same ribs. The incision is curved, starts on the sternum and proceeds laterally to the fifth or sixth interspace. It is mandatory that the internal mammary and the intercostal vessels be ligated. In the reflection of the pleura care must be taken not to cause any lacerations. Small lacerations which can be easily sutured may be of no consequence, but those large and difficult to suture will cause a pneumothorax that will render cardiac function difficult. The transpleural route, advocated by Decker, should be used only when the left pleural cavity is free of adhesions. With this approach the possibility of spreading a tuberculous infection must be considered.

The pericardium is removed always, but the epicardium is removed only when it is thickened. When the structures can be separated by digital dissection, the parietal layer is removed first, followed by decortication of the myocardium. If separation of the layer is impossible, the dissection must be done slowly and carefully until the cardiac muscle is reached.

The ideal pericardiectomy consists in removal of all the pericardium, but as this is impossible we must be satisfied with pericardial removal of the anterior, posterior, and apical part of the left ventricle. Care must be taken not to cut the phrenic nerve, even though the consequences are not serious when it is accidentally cut (Sauerbruch, Schmieden). Decortication of the right ventricle and auricles is difficult, and Schmieden and Fisher do not advise it.

Among the complications, the author emphasizes the following:

1 Laceration of the heart, usually the right side or auricles. If the laceration is not sutured well, or if left unsutured, death will occur. Acute dilatation of the heart with arrest in diastole.

2 Disturbances of the cardiac rhythm, irregularity of the pulse, auricular fibrillation, and temporary arrest of the heart. These have been reported by some authors. Except for some irregularities of the pulse, these conditions have not been encountered by the author.

3 Hemorrhage may occur after decortication, consequently hemostasis must be complete. Drainage is required in these cases. The author concludes his article by reporting his 5 cases of pericardiectomy. He obtained good results in 3 cases, in 1 case there was no improvement because the malady was too advanced, and in the last case death followed post-operative collapse.

Patients with a calcified pericardium are difficult to treat and should not be operated upon. Tengwall operated upon 3 patients with very poor results.

JOSEPH M. A. PAPE, M.D.

ESOPHAGUS AND MEDIASTINUM

Gastric Cyst of the Mediastinum ADRIAN A. EHRLER and SUSANNA ATWELL. *J Thorac Surg*, 1948, 17, 809.

The authors found reports on 27 cases of gastric cyst of the mediastinum in the literature. In only 2 instances were the patients more than 15 years of age. Nineteen patients were infants under 1 year of age and the remainder were infants between 1 and 4 years of age. The presence of gastric mucosa and its resultant secretions which are capable of digestive activity and peptic ulceration, lead to lethal complications relatively early and undoubtedly explain the paucity of such cysts in adult life.

Just how such cysts may be produced is, of course, shrouded in the same veil of obscurity that characterizes congenital abnormalities in general.

The symptoms produced by these cysts may be varied and include dyspnea from pressure and distortion of the air passages or lungs, as well as cough. Dysphagia may occur but a soft infant diet will usually pass even a distorted esophagus, however, an increase in dyspnea or even cyanosis may accompany swallowing. Hemoptysis, hematemesis, or melena may be observed, but usually these conditions signify erosion of the cyst into, or a communication of some other nature with, the air passages or esophagus.

Chief reliance for the diagnosis is placed on the roentgenograms in the posteroanterior and lateral or oblique views. The cyst is usually located in the posterior mediastinum and most often presents toward the right. Laminography may be required for the demonstration of small cysts. The serious consequences of the presence of such cysts in infants demands their removal.

The treatment of choice is complete removal of the cyst if possible. If not, destruction of any remaining mucosa is indicated. Marsupialization and prolonged drainage may occasionally have to be resorted to, and followed by attempts to destroy the mucosa. Simple external drainage is undesirable.

Fig 1 (Ehler, Atwell) Posteroanterior roentgenogram showing fluid level on right side, note hemivertebrae in upper thoracic and cervical spine

Fig 2 Lateral roentgenogram, fluid lies posteriorly
teinemia, loss of weight, and inanition are marked, due to failure of essential products of nutrition to enter the circulation

A transpleural approach is recommended, since it is adequate and safe in competent hands

A gastric cyst occurring in a boy 15 months old was completely removed through a right transpleural thoracotomy, with an entirely successful outcome, this case is reported in detail and is amply illustrated

A comprehensive review of the literature is given and a bibliography of 32 references is appended

HIRAM T. LANGSTON, M.D.

Traumatic Chylothorax R. STARR LAMPSON, J.
Thorac Surg, 1948, 17: 778

Chylothorax is, by definition, the condition which results when chyle accumulates in the free pleural space. This occurs in the presence of serious disease, such as venous obstruction to the superior vena cava, lymphatic block in filariasis, erosion of the duct or its radicals by malignant neoplasm, or tuberculosis. When chylothorax develops after direct laceration which severs the duct—as in bullet wounds, surgical accidents, fracture of adjacent vertebrae, or following indirect injury which tears it by concussion, or traction from external blows, or even coughing—there is always a latent period before symptoms appear. This is usually from 3 to 7 days, but it may be several months. The delay is the time required for the chyle to escape from the extrapleural mediastinum into the pleural space, and fill it to the point at which the volume of fluid embarrasses respiration and causes distress. This alteration of respiratory physiology may precipitate cardiovascular collapse and shock, which respond to thoracentesis. If the condition is of long duration, and frequent thoracenteses have been done, hypopro-

Fig 3 (Ehler, Atwell) Magnification of mucosa of cyst wall to show typical secreting gastric mucosa

The diagnosis of chylous effusion is established by the character of the pleural fluid. Chyle is a milky, thin fluid, with a specific gravity of 1.010 to 1.021, and alkaline in reaction. The values for electrolytes, protein, sugar, and cholesterol approximate those of the serum, but are subject to wider variations, as a result of the diet.

Chyle is a vehicle for the mobilization of proteins, which, in the presence of hemorrhage, are redistributed and made available for essential functions, it is bacteriostatic.

Traumatic chylothorax is an extremely rare disease, only 69 cases having been discovered. The ages ranged from 9 to 62 years, 47 of the 58 acceptable cases were males, 11 females. This is to be expected in traumatic disease.

The most striking feature in the management of these cases is the multitude of ingenious suggestions which have been considered or executed in treatment. Frequent thoracenteses have been used almost universally. Pneumothorax, for the purpose of discouraging the flow of chyle, has been done without great success. Instillation of sterile broth and irrigations with azochloramid and other substances, to stimulate fibrinous reaction, have been of some benefit. The phrenic nerve was crushed twice with doubtful success. The intravenous or intrasternal injection of chyle has occasionally been beneficial. Restricted diets, low in fluids, fat, and protein reduce the production and flow of chyle. Surgical drainage of the mediastinum, through the posterior approach, has been attempted in the hope that a free external flow of chyle would encourage healing of the rupture in the duct. Direct injury to the thoracic duct in the neck has resulted in external chylous fistula or in chylothorax. Both of these conditions have been controlled by ligation of the cervical thoracic duct.

When conservative methods fail, one is justified in risking a direct attack through the chest, at or below the site of rupture, with the intent to ligate the duct low in the mediastinum.

The case presented establishes the fact that low ligation of the thoracic duct is a feasible procedure. After operation, the chylothorax promptly ceased, and the patient has remained free from it for over a year. The operative procedure, which is described in detail, is rather difficult and should be reserved

for the patient who has demonstrated, by the clinical course, that spontaneous closure will in all probability not occur.

SAMUEL KAHN, M.D.

MISCELLANEOUS

The Right Thoracoabdominal Approach JOHN P. HEANEY and GEORGE H. HUMPHREYS *Ann Surg*, 1948, 128: 948

The need for an approach to the structures of the right upper quadrant of the abdomen which would give a more adequate exposure has long been appreciated. The immobility of the costal margin being the main barrier to good exposure, the authors considered a right thoracoabdominal approach, cutting across the costal margin, in answer to this problem. Following experiments in the anatomy laboratory on cadavers and on living dogs, and finally in the autopsy room, the authors considered that the procedure deserved a clinical trial.

An obese patient with gallstones was selected for the procedure. Through a long curved thoracoabdominal incision, the costal cartilage was divided between the ninth and tenth ribs, entry to the chest was through the ninth interspace, and the abdomen was opened through a curved radial incision in the right diaphragm. The right lobe of the liver was gently rotated into the chest and all the structures in the region of the porta hepatis were well exposed. The gall bladder was easily removed. The only difficulty encountered was in closing the divided diaphragm at the transected costal margin. It is suggested that a rib resection would make the closure less difficult.

This approach is offered as a useful one in secondary and tertiary operations upon the biliary tree, in pancreaticoduodenal operations, in portacaval anastomosis, and in removal of portions of the right lobe of the liver, since the inferior vena cava can be controlled above as well as below. It is also suggested that occasionally it might be easier to perform cholecystectomy through the chest than through the abdomen, as splenectomy and gastrectomy are sometimes carried out. If unexpected technical difficulties are encountered in the right upper quadrant and additional exposure would be advantageous, the approach can be used as an adjunct to the ordinary right upper quadrant incisions.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Peripheral Sensorial Innervation of the Digestive Tract (Las vías sensoriales periféricas del tubo digestivo) I DE CASTRO, P DE SALA, and J M BLANCO *Rev espan enferm ap digest*, 1948, 7 785

The authors discuss the innervation of the abdominal viscera after observing the effects of distention of the abdominal viscera on the dilatation of the pupils of cats and after cross nerve anastomosis. The distribution of the afferent and efferent vagal and splanchnic nerves is very well illustrated with many interesting figures.

WILLIAM E RICKETTS, M D

Control of Gastric Secretion GEORG KARLSON *Brit M J*, 1948, 2 1091

The author reviews the physiological concepts concerning the control of gastric secretion and attempts to separate the proved facts from unjustified speculation. The results of this analysis are summed up as follows:

"If tentatively we try to link together the pattern of facts as they are seen so far, the contours above the horizon of unjustified speculation are as follows: Gastrin is contained in the pyloric mucosa, and in man and pigs, in the duodenum as well. This agent is liberated by vagus impulses or when chemical substances such as food come into contact with the mucosal regions concerned. The liberated gastrin is carried by the blood to the fundic mucosa, where it causes some change so that histamine is liberated in quantities sufficient to stimulate the parietal cells. In this picture gastrin enters as a common factor in the nervous, gastric, and intestinal phases of acid gastric secretion."

The author admits that a great deal of work remains to be done before this view can be accepted even by those who are suggesting it as a working hypothesis.

HAROLD LAUFMAN, M D

Histologic Basis for Anacidity in Gastric Disease LEWIS W GUISS and FRED W STEWART *Arch Surg*, 1948, 57 618

The authors discuss the etiology of gastric anacidity and state that it is variously ascribed by different authors to atrophy of the gastric mucosa, congenital defect, gastritis, avitaminosis (B), idiopathic causes, and gastric carcinoma. However, little correlation has been found between the size of the gastric carcinoma, the site of the neoplasm, and the quality of the secretion.

This report is concerned with an attempt to relate the anatomic findings with the degree of gastritis and achlorhydria in a group of stomachs resected for duodenal ulcer (32), prepyloric ulcers (19), ulcer of the gastric fundus (20), carcinoma of the prepyloric area (92), and carcinoma of the gastric fundus (113).

The size and site of the gastric lesions were also correlated.

Considerable variation in the parietal cells in these stomachs was noted. Frequently the cells were apparently integrate from a histological standpoint, but when figures from gastric analyses were correlated, it became evident that unless the acidophilic granules in the cells could be clearly made out in properly stained sections the parietal cells were probably physiologically inactive.

The number of parietal cells present was correlated with the intensity of the existing gastritis. The coefficient of correlation was -0.719 ± 0.020 , signifying that as the intensity of chronic atrophic gastritis in the fundus increases, there is a proportionate decrease in the number of parietal cells.

The number of "functional" parietal cells present in the fundus mucosa was correlated with the highest figure for free hydrochloric acid obtained by fractional analysis of gastric material from the same patients. Because of the possibility of inhibition of secretion of hydrochloric acid in the carcinomatous stomachs by a gastric secretion inhibiting substance, the stomachs were divided into two groups, one containing those with peptic ulcers, and the other those with cancer.

In the ulcer group the coefficient of correlation between the number of parietal cells present in the fundus mucosa and the highest figure for free hydrochloric acid obtained by fractional analysis of gastric material from the same patients was $+0.622 \pm 0.083$. This high positive correlation signifies that the more parietal cells present, the greater the tendency toward high amounts of free hydrochloric acid.

The correlation coefficient between the number of parietal cells present in the fundus of stomachs with cancers and the production of free hydrochloric acid was even higher, i.e. $+0.718 \pm 0.0413$, a highly significant positive correlation. Therefore, the production of hydrochloric acid in the cancerous stomach is directly proportionate to the number of normal-appearing parietal cells present in the fundus of these stomachs. The coefficient of correlation was only slightly higher in cancerous stomachs than in the ulcerous stomachs. No correlation could be obtained between the location of a cancer in the stomach and the production of free hydrochloric acid. The figures also showed that in cases of duodenal and antral ulcers, the fundus is essentially devoid of chronic atrophic gastritis whereas in cases of ulcer of the fundus, moderate gastric changes are found.

Little or no relation was found between the size of the lesion and the free hydrochloric acid except that when the lesion was large enough to destroy or affect the major portion of the fundus mucosa, anacidity naturally resulted. Chronic atrophic gastritis and parietal cell deficiency are the primary causes of anacidity and explain the greater incidence of ana-

cidity with increasing age in the general population

ERNEST D. BLOOMENTHAL, M.D.

The Management of Massive Gastroduodenal Hemorrhage FREDERICK H. AMENDOLA Ann Surg, 1949, 129, 47

The term "massive gastroduodenal hemorrhage" should apply only to acute rapid loss of blood causing hemorrhagic shock. Unless this type of hemorrhage is considered separately from those of less magnitude, the vital statistics of such cases are hopelessly confusing.

Such hemorrhages produce an immediate rapid diminution in blood volume and hypotension which may produce acute circulatory failure or heart failure. Prolonged severe hypotension from acute hemorrhage may cause irreparable damage to vital organs, particularly in older patients.

Although the figures for conservative management vary greatly, certain facts can be obtained from them. The author reviews reported series of cases by other authors and cases from his own hospital. Expectant treatment resulted in a 19 per cent mortality of patients over 45 years of age and in a mortality of 15 per cent for the entire group of patients with massive hemorrhage. Of those treated surgically, there was but 1 death, or a postoperative mortality of 9 per cent in the group operated upon within 48 hours. Three patients were treated expectantly, to a point where nothing more could be done, and were then operated upon, all 3 of these patients died.

The plan of management is based upon certain deductions from statistical studies, as follows: (1) indiscriminate emergency surgery for ulcer hemorrhage should be strongly condemned, (2) the risk of lethal hemorrhage in younger patients is relatively small, and emergency operative intervention in this group will not often be necessary, (3) all serious bleeders above the age of 45 are potential candidates for emergency operation, (4) severe ulcer pain preceding the hemorrhage or persisting after hemorrhage is a serious symptom, usually indicating deep penetration, or impending or localized perforation, (5) in the presence of pyloric stenosis hemorrhage is more likely to continue or recur, (6) the patient over 50 years of age, who is bleeding from a chronic gastric ulcer, is most likely to die of uncontrollable hemorrhage, (7) surgical intervention, when indicated, carries the least risk during the first 48 hours of active bleeding, (8) in the older group, recurrent severe bleeding in a patient who has just recovered from a previous episode is of the gravest prognostic importance, and (9) the mortality from late surgical intervention is prohibitive.

Based upon these premises, the author has outlined a plan of management of such cases:

1. Active treatment of the patient in shock is begun at once without subjecting the patient to any but the most cursory physical examination.
2. Nothing is permitted by mouth except small sips of water or cracked ice.

3. Blood replacement is begun at once. Plasma may be used, but only to take the place of blood until blood is obtained.

4. Blood is drawn for hematocrit, prothrombin, and blood urea nitrogen determinations, as well as for typing and blood counts.

5. Repeated or continuous transfusion is required as long as the systolic pressure remains below 90 or the pulse over 130, or both.

6. When restorative measures have been initiated, a rapid physical examination is made and a history secured in an attempt to ascertain the most probable source of bleeding.

7. In the absence of a definite history of ulcer in a patient who is bleeding uncontrollably, and in whom surgical intervention appears likely, every reasonable effort is made to establish a diagnosis. This should include examination of the esophagus, stomach, and duodenum by roentgenography, if necessary. Though a patient in shock should not be subjected to this procedure under any circumstances, bleeding of itself does not contraindicate the ingestion of barium and early examination.

8. If the presence of esophageal varices is definitely excluded, a small caliber indwelling tube is passed through the nostril into the stomach, the stomach is lavaged with saline, and continuous suction is applied.

9. Opiates or barbiturates, or both, are given in doses adequate to control restlessness. Morphine occasionally produces nausea and should be given cautiously.

10. Blood pressure and pulse are recorded at half-hour intervals.

11. All fluid, amino acid, vitamin, sugar and salt requirements are met by intravenous infusion and transfusion during the period of profuse bleeding.

12. *Indications for operation.* When causes of bleeding other than chronic ulcer have been excluded with reasonable certainty, (a) patients over 50 years of age who continue to show a rapid pulse, drop in blood pressure, slight air hunger, and other signs of continued bleeding despite repeated transfusions over a period of 24 hours, require surgical intervention, (b) younger patients who continue to bleed profusely and who remain at shock levels despite repeated transfusions over a period of 48 hours require surgical intervention, (c) recurrence of massive bleeding in the older ulcer patient demands immediate operation, (d) massive hemorrhage superimposed upon a known pyloric obstruction requires surgical intervention, (e) simultaneous hemorrhage and perforation obviously call for immediate operation, and (f) patients who are first seen after many days of severe continuous or repeated hemorrhage are extremely poor surgical risks and are best treated expectantly. Simple high jejunostomy under local anesthesia for feeding purposes may be of value.

Because of the many difficulties of operation in such cases, they should only be delegated to the most experienced of abdominal surgeons. No patient should be subjected to operation unless with

massive blood transfusion and modern anesthesia, he can be safely considered for major gastric surgery. If this cannot be accomplished, he is best treated expectantly.

A simple ligation of the bleeder, or ligation of vessels supplying the ulcer, is usually a useless type of surgical procedure in these cases, and a form of resection is almost invariably necessary.

FREDERICK C HOEBEL, M D

Gastrojejunal Colic Fistula HENRY H. FAXON and WILLIAM G. SCHOCH, JR. *N. England J. M.*, 1949, 240: 81

The findings in 9 cases of gastrojejunal colic fistula are presented, and the literature on the subject is reviewed.

Usually, the symptoms are attributable to the secondary effects of diarrhea induced by the reflux, into the upper jejunum and stomach, of irritating contents of the large bowel. Passage of gastric material into the colon through the fistula in the reverse direction is delayed, as a rule, by a valve-like action of the jejunal mucosa.

The treatment of gastrojejunal colic fistulas is surgical and consists of removing the fistula, restoring bowel continuity, and correcting the ulcer diathesis.

Preparation of the patient for excision of the fistula should include the institution of an ascending colostomy, as recommended by Pfeiffer, as a preliminary procedure in all patients whose general condition is unsatisfactory.

The tendency in these patients to reactivate an ulcer after an excision of the fistula and restoration of intestinal continuity is so strong that unless corrective surgical measures have been carried out at the earlier operation they should be adopted before the patient is finally discharged from the hospital.

A case is cited for the first time in which, after excision of the fistula, transthoracic vagotomy was used as the definitive treatment of the ulcer diathesis. This patient was asymptomatic a year after the vagus resection.

BENJAMIN GOLDMAN, M D

New Problems in the Origin of Gastric Ulcer (Neuere Probleme in Beziehung zur Magengeschwülersentstehung) G. VON BERGMANN. *Deut. med. Wschr.*, 1948, 73: 621

The author refers to his theories which he first expounded in 1913. At that time he stated that he suggested that the ulcers of the stomach had their origin in certain nervous and spastic changes in the gastric blood vessels. Although there have been numerous contributions on the origin of gastric ulceration, he still believes that this condition finds its origin in certain unexplainable alterations in the sympathetic nervous system. This does not presuppose a simple imbalance between the craniosacral and the thoracolumbar outflows, for he states that he has never observed any person who might truly be classed as a parasympathetic individual.

Furthermore, he cites the work of Cushing and others who have observed gastric ulceration follow-

ing manipulation in the midbrain. He also cites the work of his coworker, Kauffman, who was able to produce gastric ulceration by the subcutaneous injection of certain proteins into the back of a dog. The effects which Rosenow was able to produce on the basis of the theory of focal infection, he believes, were due to its effect on the nervous elements of the gastric wall.

He explains that the lesser curvature of the stomach is most frequently affected by ulceration, not because of the course of the "Magenstrasse," but because of the difference between the vascular and nervous distributions in the stomach. The discussion is followed by a citation of various cases in which ulceration has followed certain psychological experiences. One of the patients showed recurrences with definite psychological trauma, and therapeutic results were obtained by the alteration of the situation.

WILLIAM C. BECK, M D

Surgical Methods in the Treatment of Gastroduodenal Ulcers (Métodos quirúrgicos para mejorar los resultados en el tratamiento de las úlceras gastroduodenales) RICARDO LOZAÑO BLES. *Rev. espan. enferm. ap. digest.*, 1948, 7: 704

In 324 cases of nonperforated gastrojejunal ulcer, subtotal gastric resection was done. Of these ulcers, 63 per cent were gastric, 37 per cent were duodenal, and 18 per cent were jejunal. The surgical mortality in the first 100 cases was 12 per cent, while in the last 100 it was 2 per cent. Recurrence of the ulcer took place in only 2 cases.

WILLIAM E. RICKETTS, M D

Surgical Methods in the Treatment of Gastroduodenal Ulcers (Métodos quirúrgicos para mejorar los resultados en el tratamiento de las úlceras gastroduodenales) J. SOLER ROIG. *Rev. espan. enferm. ap. digest.*, 1948, 7: 749

The author found that subtotal gastrectomy continues to be the elective treatment for noncomplicated gastroduodenal ulceration. Recurrence of the ulcer was observed in 2 per cent of 315 gastrectomized patients. Forty patients were subjected to vagotomy, and in 19 of these it was done transthoracically. In 1 patient an anastomotic ulcer recurred. The author does not include evidence in this case that the vagotomy was complete.

Vagotomy plus gastrectomy is advised when there is gastric retention due to deformity or stenosis in the duodenum. The postoperative symptoms after vagotomy, such as diarrhea, anorexia, and distention of the stomach, were easily controlled by treatment.

WILLIAM E. RICKETTS, M D

Surgical Methods in the Treatment of Gastroduodenal Ulcers (Métodos quirúrgicos para mejorar los resultados en el tratamiento de las úlceras gastroduodenales) R. VERA LÓPEZ. *Rev. espan. enferm. ap. digest.*, 1948, 7: 575

The author reports a series of 531 gastric operations for peptic ulcer. Twenty-eight gastroenterotomies were done with a mortality in 5 cases. The

cause of death in these cases was as follows gastric tetany (1), perforation (1), pneumonia (2), and an unknown cause (1). Subtotal resection of the stomach was carried out in 503 cases with a mortality in 67. The localization of the ulcer was in the stomach in 43.3 per cent of the cases, in the duodenum in 52.1 per cent, and in the jejunum in 2.6 per cent.

The mortality in subtotal gastrectomy varied considerably with the modern surgical improvements in techniques as well as with preoperative and postoperative care. While the mortality in 1934 was above 10 per cent, there were no fatal cases in 1947 and 1948. The most frequent causes of death were peritonitis and upper respiratory infection.

WILLIAM E. RICKETTS, M.D.

Partial Gastrectomy for Peptic Ulcer. T. W. MUMPRISS and Sr. J. M. C. BIRT. *Brit. M. J.*, 1948, 2, 1095.

This series consists of 248 patients who had undergone partial gastrectomy for peptic ulcer. An attempt was made to assess the merits of four types of anastomosis. Type I was an end-to-side anastomosis with an antecolic proximal loop attached to the greater curvature. Type II was an end-to-side anastomosis with a long antecolic proximal loop attached to the lesser curvature with a valve and a small stoma. Type III was an end-to-side anastomosis with a short postcolic proximal loop attached to the lesser curvature with a small valve and a small stoma. Type IV was an end-to-end anastomosis of the Billroth I type joining the duodenum to the greater curvature of the stomach.

The overall mortality for this series was 2 per cent. In the main, the patients who have had a partial gastrectomy for ulcer are satisfied. Seventy-three per cent are symptom-free and 22 per cent have slight symptoms which are not severe enough to make them dissatisfied. Approximately 5 per cent either have a poor functional result or are dissatisfied. Analysis of the cases whose results are listed as fair or poor led to three conclusions: (1) that pain of the ulcer type is most unusual, and in the patients followed by the authors no anastomotic ulcers have been proved, (2) that the departure from a normal digestion is due to the incidence of what is described as "side effects" or postcibal distress. The symptoms of which the patients complain are nausea and, less often, vomiting, a feeling of distention, lassitude, sweating, and attacks of diarrhea. These come on at varying periods during or after a meal, (3) that fats and fried food are the articles of diet most likely to cause trouble.

The more troublesome and chronic the original ulcer, the more tolerant is the patient of minor functional disturbances in his postgastrectomy result.

Anastomosis of the afferent loop to the greater curvature leads to a high incidence of proximal loop filling. There is nothing to choose between the functional results of the other three anastomoses employed. The long proximal loop needed in the

antecolic operation is more likely to lead to complications than the short proximal loop used in the retrocolic operation. The Billroth I anastomosis is probably the safest of all as it has no afferent loop. Because of the risk of stenosis, this is not a suitable anastomosis after gastrectomy for duodenal ulcer.

In this series there is no evidence to support the view that gastrectomy for duodenal ulcer gives worse results than for gastric ulcer. Eighty per cent of operations for duodenal ulcer were classified as good as opposed to 58 per cent for gastric ulcer.

HAROLD LAUFMAN, M.D.

Neurogenic Tumors of the Stomach. R. L. CANNEY. *Brit. J. Surg.*, 1948, 36, 139.

Benign tumors of the stomach are rare. The two types of benign nerve sheath tumors that occur in the stomach are the neurilemmoma and the neurofibroma. The former is usually solitary and is but rarely associated with von Recklinghausen's disease, the latter, however, is frequently multiple and is most often associated with von Recklinghausen's disease. Any of the characteristic stigmata of von Recklinghausen's disease, such as cutaneous nodules, pigmented areas in the skin, mental deficiencies, or skeletal changes, may be present in the individual case.

Apart from the usual association with von Recklinghausen's disease, the distinction between the two types of tumor is entirely a histological one, depending largely on a relative preponderance of fibrous tissue. The distinction, however, is not entirely academic since the neurilemmoma has a much greater tendency toward malignant degeneration than does the neurofibroma.

Sarcomatous changes in the neurilemmomas are not infrequent. The differentiation between benign and malignant tumors may not be easy and depends largely on the cellularity of the tumor and the presence of infiltration of the gastric wall. Generally, the tumors tend to remain locally malignant for long periods and metastasize only in the latest stages so that the prognosis even in the malignant form of the disease is good.

The tumors are usually small (less than 6 cm. in diameter), solid, sometimes lobulated, and attached to the gastric wall by a broad base although they may be pedunculated. The mucous membrane covering the tumor is vascular and often ulcerated. A characteristic feature is the deep punched out ulceration on the surface of the tumor which accounts for the characteristic niche seen on the roentgen film.

There are no characteristic features which distinguish these tumors clinically. The symptoms will depend to a certain extent on the position and situation of the tumors in the gastric wall. Hemorrhage, the most common symptom, is usually considerable and occurs at intervals, the patient being well in the intervening periods but with a steadily progressive anemia. The tumor when situated near the pylorus tends to become pedunculated and to prolapse through the lumen, which gives rise to recurrent

abdominal pain and vomiting. On clinical examination there are few signs of significance that are usually detected except possibly the presence of a palpable abdominal mass. The patients are in good general health and if a benign tumor of the stomach is suspected, they should be examined carefully for the presence of von Recklinghausen's disease.

In the absence of von Recklinghausen's disease, the final diagnosis in these cases will probably not be made until microscopic examination of the tumor has been performed, although its presence may be suspected. If a tumor is suspected from the clinical examination, the patients should certainly be subjected to laparotomy, especially in view of the possibility of malignant changes. Wide surgical excision is advisable although local excision may be preferable for small tumors. Partial gastrectomy will usually be necessary, the extent of the resection depending upon the size and location of the tumor. With such treatment the prognosis is excellent even in patients in whom malignant changes have occurred.

ORVILLE F. GRIMES, M.D.

Argentaffinoma of the Gastrointestinal Tract

DOUGLAS R. K. REID *Brit J Surg*, 1948, 36: 130

Approximately 85 per cent of argentaffinomas occur in the ileocecal region, and of these the great majority are found in the appendix. They are found with decreasing frequency in the ileum, jejunum, duodenum, colon, and stomach.

In the small bowel, a purely submucous tumor may be sessile or polypoid. When it invades the muscle coats, a highly characteristic feature consists in buckling of the bowel wall with resulting invagination of the tumor toward the lumen. This distortion is due to contraction of the fibrous and abundant elastic tissue of the stroma, especially in the subperitoneal coat, and it constitutes the mechanism whereby even very small carcinoids may produce intestinal obstruction. The growth may assume an annular form, although it does not, as a rule, completely encircle the bowel wall. This type produces obstruction partly by stenosis and partly by buckling. Intussusception has resulted from the presence of a polypoid tumor, and in other cases obstruction has been the result of adhesions of coils of bowel in the vicinity of a carcinoid, particularly when this has invaded the mesentery.

All argentaffinomas have the microscopic picture of carcinoma simplex, and in all, whether benign or malignant, the cellular features are constant. Therefore, it is not always possible to distinguish the benign and the malignant forms on the basis of histology alone. It is probably sound to regard all carcinoids as at least potentially malignant and to classify them according to their behavior as localized, invasive, or metastasizing. Malignancy in the form of local invasion of the mesentery or of actual metastases is extremely rare in the appendicular carcinoid. Extra-appendicular tumors, however, which occur at a later period in life, are much more prone to display obvious malignancy.

Metastasis takes place chiefly to the lymph nodes of the mesentery, of which one or many may be involved. Secondary deposits have been found in the liver, and in a few instances in the retroperitoneal tissues, lung, pleura, brain, spinal meninges, pancreas, and inguinal lymph nodes. Both primary and secondary tumors grow very slowly, and cases are on record in which secondary deposits have been observed over periods of years without apparent progression.

Recurrent attacks of colicky pain and vomiting associated with a history of flatulent dyspepsia constitute a common set of symptoms. Bleeding from the bowel is uncommon because of the infrequency of ulceration, but diarrhea is a constant and unexplained symptom.

The treatment of benign argentaffinomas requires no special consideration in that local excision is adequate. In the malignant form, the extremely slow growth of both primary and secondary tumors justifies strenuous efforts at complete extirpation, yet at the same time it condones, in poor risk patients, measures which would be regarded as incomplete and ill-advised in the treatment of adenocarcinoma. Thus, excision of the primary tumor is not necessarily contraindicated by lymph node, peritoneal, or even hepatic metastases.

ORVILLE F. GRIMES, M.D.

Distribution of Gastric Changes Accompanying

Gastric Cancers in Various Locations. LEWIS

W. GIUSS and FRED W. STEWART *Arch Surg*, 1948, 57: 624

This report considers the importance of the variations of location in the distribution of gastritis. Many authors have reported the finding of pangastritis in all specimens of gastric cancer and antral gastritis in the large majority of gastric and duodenal ulcers. Cancers arise most commonly in the pyloric area and are more frequent at this site in younger persons. The degenerative changes of chronic atrophic gastritis are thought to be much more pronounced in the pyloric gland area, especially along the lesser curvature of the body of the stomach, and to be more or less absent along the greater curvature of the body and in the cardiac portion of the stomach. They have already been proved to increase in amount and intensity with advancing age.

The authors attempt to answer the following questions:

1. Is there a differential distribution of chronic atrophic gastritic changes present in the gastric mucosae of persons within the age range for gastric cancer?
2. Does cancer of one portion of the stomach develop earlier than that of any other portion?
3. Is there any difference in the distribution and intensity of the gastritic changes apparent in carcinomas of the various portions of the stomach, or is the "pangastritis" of carcinomatous mucosae a fact?
4. What gastritic changes appear consistently in association with peptic ulcers (a) of the duodenum, (b) of the pyloric area, and (c) of the fundus?

5 Do the changes found in "ulcer stomachs" vary significantly from those found in "cancer stomachs," and in a control series of "normal stomachs" from persons in the same age range?

This study is based upon observations of normal stomachs (48) in the cancer age range, carcinomas arising in the pylorus (92), carcinomas of the fundus (67) excluding the "surgical cardia", carcinomas of the "surgical cardia" (46), duodenal ulcers (32), peptic ulcers of the pyloric area (19), and peptic ulcers of the fundus gland area (20). The pertinent factors studied were mucosal thickness, the type of glands and constituent cells with reference to location within the stomach, the number and size of lymphoid aggregates and follicles, the amount of leucocytic infiltrate, the amount of intestinal metaplasia, and the amount and degree of dedifferentiation of specialized glands (pyloric gland heterotopia).

The mean age and the mean mucosal thickness in millimeters of the various groups are given in Table I.

The mean age of the patients with duodenal ulcer was found to be significantly less than that of all the others. Cancer does not tend to develop at an earlier age in one specific part of the stomach than in the other parts. No significant differences were found in the mean thickness of the pyloric and fundic mucosae in the various conditions.

Examination of the control group of 48 normal stomachs from persons dying in the gastric cancer age range (from 40 to 79 years) showed that there was a low mean incidence of intestinal metaplasia, and dedifferentiation of specialized glands, with no significant difference in the amount found in the pyloric and fundus gland area. There was a slight to moderate amount of leucocytic infiltrate and lymphoid aggregates present in the same group, with a definitely decreased amount present in the fundus as compared to the pyloric area.

The average gastric mucosa of normal persons reaching the gastric cancer age measures around 1.00 mm in thickness. There is a slight amount of intestinal metaplasia and glandular dedifferentiation scattered evenly over the pyloric and fundus areas. The only difference between the fundus and pyloric areas is that the amount of leucocytic infiltrate and lymphoid aggregates, small in the fundus area, is slightly but significantly increased in the pyloric area. This makes necessary the assumption that chronic atrophic gastritis occurs with equal frequency and intensity in the pylorus and fundus of persons in the gastric cancer age range.

The distribution of carcinomas in this study is interesting because it shows 98 carcinomas of the pylorus and 113 carcinomas of the fundus (including the cardia). Formerly pyloric carcinomas were listed as being more frequent, probably because the majority of cardiac carcinomas were considered inoperable. These new figures based on a series of resected stomachs reflect the extension of operability of gastric carcinomas by the addition of total gastrectomy and transthoracic cardiectomy to the older procedures.

TABLE I — MEAN AGES AND MEAN MUCOSAL THICKNESSES

Group	Number of Cases	Mean Age	Mean Mucosal Thickness Mm	
			Pylorus	Fundus
A Control	48	54.2	1.05	1.09
B Cancer of pyloric area	92	58.5	0.94	0.99
C Cancer of fundus	67	56.5	1.00	1.03
D Cancer of cardia	46	58.3	0.95	1.02
E Duodenal ulcer	32	45.0	1.04	1.12
F Pyloric area ulcer	19	57.2	0.91	1.06
G Ulcer of fundus gland area	20	55.7	1.02	0.96

The presence of a carcinoma in the stomach, either pyloric or fundic, was associated with a moderate significant increase in intestinal metaplasia and glandular dedifferentiation. The intensity of the changes present in the pylorus and the fundus was essentially the same although the amount of leucocytic infiltrate and lymphoid aggregates present in the pyloric area was not increased by the presence of cancer in either the pylorus or the fundus, however, the amount of infiltrate in the fundus (low in the control group) was so increased that the amounts were essentially the same in both areas (Table III). The degenerative and inflammatory changes are severe in the mucosa surrounding any gastric lesion.

In the 48 cases of carcinoma of the cardia, the pyloric mucosa showed the same moderate significant increase in intestinal metaplasia and the same lack of increase in the amount of infiltrate and lymphoid aggregates as in cases of carcinoma of the prepyloric and fundus areas. However, the slight increase in metaplasia, glandular dedifferentiation, leucocytic infiltrate and lymphoid aggregates which occurred in the fundus in the presence of carcinoma of the

cardia (the mucosal area nearest the carcinoma) was not significantly increased when compared with the amount found in the control group, and was significantly less than the amount found in the presence of carcinoma of the fundus.

One concludes then that there is chronic atrophic gastritis of moderate degree throughout the stomach harboring a cancer in any location except that when the carcinoma is in the cardia the changes are less notable in the fundus.

The group of 32 patients with duodenal ulcer showed no increase in intestinal metaplasia or glandular dedifferentiation as compared with the control group, in fact, there was a consistent decrease in metaplastic changes in the fundus although this decrease was not statistically significant because of the small number of specimens studied. There was a definite increase in the amount of leucocytic infiltrate and lymphoid follicles in the pyloric area in this group, but there was, again, a significant decrease in these factors in the fundus. The presence of a duodenal ulcer appears to have little or no association with degenerative changes in the gastric mucosa.

In the group of stomachs harboring a peptic ulcer in the prepyloric area there was a significant moderate increase in the amount of intestinal metaplasia, leucocytic infiltrate, and lymphoid aggregates limited to the pyloric mucosa as compared with stomachs from the control group. In a comparison of the prepyloric ulcer group with the duodenal ulcer group, the only real difference found was an increase in the infiltrate in the fundus, which was sufficient to bring it up to the control level. The presence of a prepyloric ulcer, then, is associated with mild atrophic gastritis and gastric changes near the ulcer.

The group of 20 stomachs with ulcer in the fundus gland area presented a radically different picture. Here there was a significant moderate increase in intestinal metaplasia, glandular dedifferentiation, leucocytic infiltrate, and lymphoid aggregates in both

parts of the stomach as compared with the control group. These changes were so pronounced that the mucosae of the group could not be distinguished from those of the pyloric and fundic cancer groups. The presence of a peptic ulcer in the fundus gland area of a stomach is therefore associated with a generalized chronic atrophic gastritis of moderate degree, essentially the same as in the cancer groups.

ERNEST D. BLOOMENTHAL, M.D.

One Thousand Resected Stomachs (1,000 resezierte Mägen) HERMAN ROER *Chirurg*, 1948, 19: 447

Histologic sections from 1,000 resected stomachs were studied. In the majority of cases the macroscopic diagnosis of ulcer was proved by histologic study, in others the macroscopic diagnosis of carcinoma was proved. In a small number of cases the macroscopic diagnoses presented difficulties and in these a diagnosis of carcinoma had to be ruled out. The histologic diagnosis in the 1,000 cases was as follows: ulcer, 871 cases and carcinoma, 129 cases.

Of the 871 ulcers, 41.5 per cent were gastric and 56.3 per cent were duodenal ulcers, 2.2 per cent of ulcers were both gastric and duodenal. Eighty-eight per cent of patients were males and 12 per cent were females. Fifty-four per cent of duodenal ulcers occurred in patients from 30 to 45 years of age and 67 per cent of gastric ulcers occurred in patients from 35 to 55 years of age.

Of the 129 cases of carcinoma, 7 per cent were found to be ulcer-carcinomas. Seventy-seven per cent of carcinomas occurred in patients between the ages of 51 and 70 years of age, the peak lying between the ages of 51 and 60 years. Seventy-two per cent of patients with carcinoma were males and 28 per cent were females.

JOHN L. LINDQUIST, M.D.

Appraisal of Oral Streptomycin as an Intestinal Antiseptic, with Observations on Rapid Development of Resistance of *Escherichia coli* to Streptomycin JOHN S. LOCKWOOD, ALFRED D. YOUNG, McLEMORE BOUCHELLE, THOMSON R. BRYANT, JR., and ALFRED J. STOJOWSKI *Ann Surg*, 1949, 129: 14

Twenty-four cases of large bowel lesions of various types were studied. Careful bacteriological examinations were made of stools for the coliform group, the intestinal streptococci, and the clostridia. Various groups were compared, one receiving 0.25 gm of streptomycin every 6 hours, one, 1.0 gm every 6 hours, and one, 1 gm of sulfathaladine plus 0.25 gm of streptomycin every 6 hours.

With 1 gm of streptomycin per day, 47.7 per cent of cases showed no response in the *Escherichia coli* colony counts, and 52.3 per cent showed a significant response, in the streptococci group, 87.7 per cent showed no response. In the clostridia group, 38.0 per cent showed no significant response, 22.2 per cent showed a temporary reduction in the colony count, and 38.9 per cent a prolonged reduction.

There was no significant difference between the group receiving 1 gm of streptomycin in 24 hours

and in the group receiving 4 gm. Likewise, although the series was small, the addition of sulfathaladine did not improve the results.

It has been reported that lowering the bacterial count with streptomycin may lower the prothrombin time. This was not confirmed, except by a very slight prolongation of prothrombin time in several of the cases.

The maximum effect of the streptomycin varied in the cases which showed response. For *Escherichia coli*, the maximum effect was between the second and fourth days, and for the clostridia group the maximum effect of streptomycin was between the second and seventh days. Following the maximum effect, there was a rapid return to the pre-treatment level in most cases.

None of the toxic effects that occur with parenteral streptomycin were observed with oral streptomycin.

The *Escherichia coli* group were investigated with relation to the development of resistance to streptomycin which begins within 48 hours of beginning treatment. Prior to treatment the isolated *Escherichia coli* group were sensitive to, and completely inhibited (except in one case) by 19 units of streptomycin per cubic centimeter. After treatment they became resistant to at least 156 units per cubic centimeter, except in one case which required 6 days to become resistant.

A prozone phenomenon was noted in which the treated *Escherichia coli* which were not inhibited by less than 156 units per cubic centimeter, and were inhibited by concentrations of 156 to 2,500 units per cubic centimeter would grow well when the streptomycin concentration was elevated further to between 2,500 and 10,000 units per cubic centimeter. This is important in relation to stool assays of streptomycin on patients getting 1 gm. every 4 hours. The levels within 48 hours varied from 4,800 to 9,600 units per gram of wet stool.

FREDERICK C. HOEBEL, M.D.

The Occurrence of the Gas Stoppage Sensation in Acute Obstruction of the Ileum. E. LAWRENCE KEYES. *Surgery*, 1949, 25: 47.

In the present article, the author states that the onset of acute obstruction of the ileum is manifested by pain beginning in the middle of the abdomen, accompanied by a downward urge, and persisting for hours, despite defecation. Pain of this type is characterized by a sensation of gas stoppage. After a period of hours, vomiting occurs and certain of these symptoms usually disappear. The author limits his study to the early hours of pain, prior to vomiting.

The characteristics of the pain at onset are presented as they appeared in the case histories of 6 patients with acute obstruction of the ileum. In 4 of the patients the obstruction arose internally, as the result of strangulating intraperitoneal bands or volvulus of the ileum, in 2 of the patients obstruction arose externally, in strangulated inguinal or femoral hernias. The ileum was found to be gangrenous at operation in 4 of the patients and resection of the

ileum was performed, in 2 of the patients the ileum was viable at operation.

All 6 of the patients in this series had acute obstruction of the ileum, evidenced by pain (epigastric, paraumbilical, hypogastric, or generalized) beginning in the midline of the abdomen, accompanied at first by a downward urge following enemata or laxatives, trips to the toilet, or defecation at an unusual time, and persisting despite defecation and enemata for an average period of 10 hours (the shortest, 1½ hours and the longest, 24 hours) before vomiting occurred.

The author believes that acute obstruction of the ileum should be suspected in all patients who have suffered pain of this description for as long as 8 hours when first seen, even though vomiting has not occurred. Obviously, no diagnostic aid such as auscultation, rectal digital examination, leucocyte counts, scout films of the abdomen, etc., should be neglected in making the correct and early diagnosis.

JOHN E. KIRKPATRICK, M.D.

The Surgical Aspect of Meckel's Diverticulum. JOHN K. OWEN and GEORGE G. FINNEY. *South M. J.*, 1949, 42: 98.

One hundred and forty-three cases of Meckel's diverticulum were collected from the records of the Johns Hopkins, the Union Memorial, and the Women's Hospitals in Baltimore. The anomaly was found more often in males in the ratio of 15 to 10. The average distance above the ileocecal valve was 48.8 cm., the average length was 4.4 cm., and the average width at the base was 2.2 cm. Secondary diverticula were present in 9 cases. Usually the diverticula arise at the antimesenteric border, and in most cases a mesodiverticulum is present.

The presence of heterotopic tissue in the diverticulum occurred 39 times, which was a third of the cases in which satisfactory sections were made. In 33 cases the tissue was gastric mucosa, in 3 duodenal mucosa, in 2 pancreatic tissue, and in 1 case colonic mucosa.

Pathologic changes had occurred in the diverticulum of 49 patients, of which about two thirds were males. The most common pathologic change was inflammation, which was present in 44 cases, and in 20 of these there were associated adhesions. Of the cases in which heterotopic gastric tissue was present approximately half showed pathologic changes.

Sixteen patients had ulceration in the diverticulum, and, in 6 of these, hemorrhage occurred. When ulceration occurs it usually is found within the diverticulum, however, in 1 case the site of the ulcer was in the ileum. In 12 of the 16 diverticula in which there was an ulcer, gastric mucosa was present. Ulceration also occurred in 4 diverticula in which there was no gastric mucosa.

Perforation occurred 11 times, the point of perforation usually being within the diverticulum and adjacent to its neck. However, in 1 case the perforation occurred in the ileum.

According to most authors the commonest symptom of a diseased Meckel's diverticulum is the pres-

Fig 1 (Owen, Finney) Open technique of Meckel's diverticulectomy

sage of bright red blood in the stool. However, in the author's series of 49 diverticula in which disease was present, only 9 patients had a history of the passage of fresh blood. As a rule, when blood is present it is not mixed with mucus, a sign which differentiates the condition from acute intussusception.

Thirty-three of the authors' patients complained of abdominal pain. Often the pain had its origin in the periumbilical region, as a colic or a gnawing ache similar in character to that of a duodenal ulcer. The pain was usually not relieved by food intake and had no relation to meals.

In cases in which the diverticulum was symptomatic its location was usually from 50 to 60 cm above the ileocecal valve, whereas in the asymptomatic cases its location was usually near the ileocecal valve.

The correct preoperative diagnosis was made only 7 times. X-ray studies offer no help, and in the 15 cases in which studies were made there was no x-ray evidence of a diverticulum.

The surgical procedures used in treating these diverticula were as follows: routine appendectomy technique in 65 cases, clamp technique with Connell closure in 35 cases, open technique in 14 cases, partial resection with end-to-end anastomosis in 8 cases, and inversion of the diverticulum through a purse-string suture in 1 case.

The authors emphasize that the technique of treating a Meckel's diverticulum like an appendix by ligating its base, amputating it, and inverting the stump is applicable only to diverticula that have a narrow neck. Objections to the technique include the leaving behind of an island of gastric mucosa which may perforate or ulcerate, the possibility of intestinal obstruction from encroachment of the mass of ligated tissue beneath the purse-string suture upon the lumen of the small intestine, the possibility of the stump's acting as the leading point for an intussusception, and the danger of postoperative

hemorrhage from inadequate control of the copious blood supply in the wall of the stump.

The authors describe a method of resecting the diverticulum which obviates these objections. It is an open technique applicable particularly to those cases in which the mouth of the diverticulum is large. They have used the method in 14 cases with no complications (see Fig 1).

FREDERICK W. PRESTON, M.D.

Procedures Used in the Treatment of Complicated Fistulas

DONALD R. LAIRD *Am J Surg*, 1948, 76:701

A description is given of four procedures useful in the management of complicated fistulas-in-ano, and a discussion of the general principles involved is presented.

Before surgery, careful inquiry into the bowel habits of the patient may account for the difference between a good and a bad result. For example, a patient who passes frequent loose stools and who does not have well developed anal sphincter muscles would be a poor risk for a contemplated incision of the anal sphincter. Conversely, if a patient is inclined to be constipated and passes large well formed stools, incision of a large portion of the anal sphincter fibers may be performed without much risk that control of the gas and feces will be impaired. When extensive incisions of the anal sphincter are necessary the least serious loss of control occurs when the incision is made through the posterior portion of the anal musculature, while the greatest loss of control is produced when the anal sphincters and transverse perineal muscles are incised anteriorly. This is true especially in women.

The four procedures outlined are

1. The mucosal flap operation in which the flap of skin, rectal mucosa, submucosa, and circular fibers of the anorectal wall are dissected upward. The fistulous openings are closed with sutures after

the margins of the openings have been trimmed free from epithelium. This procedure is successful in patients who have relatively thick rectovaginal septa and rectovaginal openings 1 cm in diameter or less.

2 The muscle plug procedure is advocated in patients who have thin-walled, relatively avascular, rectovaginal septa, and rectovaginal openings over 1 cm in diameter. A living muscle flap of rectal wall muscle is drawn from the rectum through the rectovaginal opening and held by sutures placed in the vagina.

3 Mobilization of the rectum for combined rectovaginal and rectourethral fistulas is performed by dissecting an anterior skin flap and continuing it up into the rectum over the anterior three-fourths of the anorectum until it is well above the insertion of the levator ani muscles before the full thickness of the rectal wall is penetrated. In males the margins of the proximal rectum are grasped by forceps and the rectal wall is freed from the prostate and seminal vesicles by sharp dissection. Dissection is then continued laterally as high as possible. After the rectum has been mobilized as completely as possible the bladder and prostatic epithelium which had grown into the defect is trimmed away and the defect is closed by interrupted sutures. This procedure of mobilization of the rectum and the removal of a segment has been used successfully for rectal prolapse accompanied by carcinoma and for extensive adenomatous hyperplasia involving the entire lower rectum.

4 The operation for relaxed sphincters involves the dissection of a rectangular flap of skin past the anal verge. Sutures are then placed in the area of the separated musculature and perineal body. The viable flap of anal mucosa prevents rectal discharges from infecting the deeper parts of the sulcus. The skin is not closed.

HAROLD I. AUFMAN, M.D.

The Etiology of Chronic Ulcerative Colitis (El problema etiológico de la colitis ulcerosa grave) M. JOSE SA FLEITAS. *Rev. As. méd. argent.*, 1948, 62: 638.

A very interesting study was made of the fecal bacterial flora in 25 cases of chronic ulcerative colitis. In 13 cases a monomicrobial infection was found, in 6 cases atypical enterococcus (Bargen's type) was found, in 2 cases bacillus coli, and in 1 case each, espirochete type "eurigrafe," enterococcus, and hemolytic streptococcus. A plurimicrobial infection was found in 12 cases.

The use of vaccines, made from bacteria obtained from feces, was followed by good clinical results in 83 per cent of 13 cases, and an endoscopic "cure" in 58 per cent of the cases. There was an 81 per cent improvement of the roentgenologic signs of the disease.

WILLIAM E. RICKETTS, M.D.

Surgical Treatment of Nonspecific Ulcerative Colitis WALTER A. FANSLER and HOWARD M. FRISKMAN. *Am. J. Surg.*, 1948, 76: 713.

Surgery in idiopathic ulcerative colitis may be indicated in either the acute or chronic phase of the disease. At the present time there is no yardstick which will definitely indicate when to abandon con-

servative measures and resort to surgery. This point varies with individual opinion and experience, but it seems obvious that the more recent trend is toward earlier surgical intervention. The operations found most useful are: (1) ileostomy alone, (2) ileostomy with complete colectomy with or without removal of the rectum, (3) partial or complete colectomy with anastomosis of the ileum to the remaining segment of the colon or rectum, and (4) vagotomy.

Of particular interest is the operation of trans-thoracic vagotomy, originally performed by Dennis, of Minnesota. Four patients in the present series were subjected to this operation. These patients had a history of the disease process varying from 8 to 19 years with numerous remissions and exacerbations. In one case there had been a complete remission for almost 10 years. Vagotomy was done in each case during a period of acute exacerbation which did not respond to medical management. All of the patients showed typical x-ray changes with ulceration of the mucosa, shortening of the colon, and loss of haustrations. To date, 3 of these patients have shown marked improvement in their condition after years of prolonged illness. All have had a gain in weight with improvement in their general health. One patient showed a completely healed rectum and distal sigmoid colon 3 months after surgery. Considerable scarring was evident but the colonic mucosa was otherwise pale and normal throughout. Two of these patients still showed patchy granular areas but each examination revealed a more advanced stage of healing. The patient who showed the least improvement had a 17-year history of ulcerative colitis.

Although the observation period is still rather short, it would appear that vagotomy is of definite value in the acute fulminating type of ulcerative colitis, especially since it is in this type that the highest operative mortality had been encountered with the use of emergency ileostomy.

HAROLD I. AUFMAN, M.D.

Surgical Treatment of Chronic Ulcerative Colitis (La cirugía en la colitis ulcerosa grave) OSCAR F. NAPP. *Rev. As. méd. argent.*, 1948, 62: 634.

Napp discusses the difficulty of deciding which cases of chronic nonspecific ulcerative colitis should be considered for surgical treatment by ileostomy or colectomy. Several very interesting cases are presented, with reports of the results of surgical management in this disease.

The author concludes (1) that ordinarily chronic ulcerative colitis is not a surgical disease, (2) that operation is indicated only in the presence of complications of the disease and for "intractable" cases under medical treatment, and (3) that the elective operative procedure is a terminal ileostomy.

WILLIAM E. RICKETTS, M.D.

Malignant Tumors of the Colon and Rectum F. W. POSTLETHWAIT. *Ann. Surg.*, 1949, 129: 34.

This study comprises 441 patients observed during the 15-year period from 1931 to 1945 at Duke Hospi-

tal, Durham, North Carolina. Many facts worth noting are pointed out or re-emphasized.

Twenty and four-tenths per cent of the group had a family history of malignant tumor. Many of the patients had had previous operations following the onset of their symptoms. Hemorrhoidectomy or injection of hemorrhoids had been performed in 9 per cent of cases with existing rectal or rectosigmoid lesions. The average duration of symptoms was 8 7 months, which agrees closely with other studies.

The lesions were divided into three groups: cecum through hepatic flexure as right colon, transverse colon through sigmoid as left colon, and rectosigmoid and rectum as the third group. Acute obstruction was present in 7 per cent of the right colon and in 5 per cent of the left colon but intestinal obstruction, manifested slowly, was observed more frequently in lesions of the left colon.

Changes in bowel habits and stool were present in all patients, but the most noticeable changes were in the rectum and rectosigmoid; obstructive symptoms in patients in this group were less common than in patients with lesions of the left colon.

Although abdominal pain was the most frequent symptom in both groups of colonic lesions, it was only fifth most common in patients with tumors of the rectum and rectosigmoid.

The average weight loss in all groups was about the same, and the total average loss was 25.6 pounds.

Of 229 cases of rectal cancer, the lesion could be felt digitally in 222. Tenderness was present in approximately a quarter of the cases of colonic cancer. A palpable mass was present in 69 per cent of patients with lesions of the right colon and in 35 per cent of patients with lesions of the left colon. Distention was greatest in the left colon, but was present in only 28 per cent of cases.

Thirty-four per cent of lesions of the right colon had a hemoglobin of less than 90 gm. Stool examinations for occult blood, when made, were nearly always positive.

Roentgenographic examinations were positive by barium enema in 81 per cent of lesions of the right colon and in 88 per cent of lesions of the left colon.

The most important factors in the determination of preoperative procedures were (1) degree of obstruction, (2) alterations of nutrition and chemical balance, and (3) concurrent disease. Attainment and maintenance of an empty bowel, both preoperatively and postoperatively, was considered the most important single factor in the recovery of these patients.

Operative procedures were quite varied but followed the common trends in colon surgery for the period studied. Resectability was slightly higher in white than colored patients and appreciably higher in the female than in the male. It was slightly greater in those under 60 years than in those over this age. With four exceptions, all resected lesions were adenocarcinoma.

The postoperative mortality for all lesions dropped from 32 per cent from 1931 through 1935, to 16 per cent from 1935 through 1940, and to 13 per cent

TABLE I—THE FIVE YEAR SURVIVALS FOR RESECTIONS PERFORMED 1931 THROUGH 1940

	Total resections	Died in hospital	5 Year survivors		
			Living	Dead	%
R	26	3	11	4	57.7
RS	8	3	3	0	37.5
S	10	4	5	0	50.0
DC	7	2	2	0	28.6
SF	4	1	1	0	25.0
TC	2	0	1	0	50.0
HF	5	0	1	1	40.0
AC	6	0	1	0	16.6
C	9	3	3	0	33.3

from 1941 to 1945. The mortality of 43 per cent for palliative procedures on the descending colon is by far the highest figure and far higher than the 25 per cent mortality for resections of rectosigmoid lesions which is 5 per cent higher than that for any of the other resected lesions. The mortality rate of 10.0 per cent for lesions of the right colon is very low as compared to previous series covering earlier years.

Peritonitis was the most common cause of death following operation. Thirty-five per cent of postoperative deaths were due to peritonitis.

Five year survivals for the group operated upon from 1931 through 1940 are shown in the accompanying table.

FREDERICK C. HOEBEL, M.D.

The Selection of Patients and Anastomotic Procedures for Carcinoma of the Rectum and Rectosigmoid

R. RUSSELL BEST, *Am J Surg*, 1948, 76: 654

The selection of patients for rectosigmoidectomy and anastomosis is dependent upon several factors: (1) one should be hesitant about attempting anastomosis and favor the abdominoperineal excision in very obese, heavy set individuals, and (2) in all poor risk patients one should favor colostomy and posterior excision or abdominoperineal excision rather than an anastomotic procedure. In some cases simple colostomy combined with a selective procedure such as radium or electrocoagulation may be indicated.

The abdominal dissection with abdominal resection and anastomosis is usually selected for lesions of the rectosigmoid and for upper rectal lesions in which the lower margin is at least 7½ cm (3 inches) or more from the external anal margin. With a lesion in which the margin is below this approximate level, lateral spread over the levator fascia is a possibility and the abdominal approach does not permit adequate removal of the zones of lymphatic spread in the levator muscle and fascia. No surgical procedure should be advocated merely on the grounds that it is technically possible.

Abdominal dissection, posterior resection, and anastomosis is a procedure recommended when the

lower margin of the malignant lesion is below the $7\frac{1}{2}$ cm level, but above the 3 cm level. Abdominal dissection assures radical removal of the zone of upward spread and the posterior attack permits removal of lateral lymphatic spread in the levator fascia and muscle or direct extension into the levator muscle and fascia. These structures are not adequately removed by an abdominal dissection alone.

Posterior dissection with posterior resection and anastomosis cannot be considered adequate surgery for cancer of the rectum. It is recommended only under special circumstances, as an escape from a higher mortality in the aged and in a few of the poor risk cases.

A small series of 33 consecutive cases is reported by the author. Various procedures were carried out on the patients. The author drained the retrorectal space in the hollow of the sacrum via the posterior approach in every case of low anastomosis. Following the removal of this drain a draining sinus was present for some days or weeks and at times feces appeared. These sinuses may prove stubborn and annoying for several months. Incontinence has not been a troublesome factor in some cases, but it cannot be denied that the sphincter many times seems to lack its original energetic tone. This is true particularly when the resection and anastomosis have been done posteriorly in the more feeble individuals in their late seventies or eighties. In 2 cases the feces collected between the sphincter area and the line of anastomosis and the patient was unable to expel the feces without an enema. This difficulty lasted for several weeks.

HAROLD LAUFMAN, M D

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

The Serum Bilirubin during the Course of Icterus

H DEENSTRA *Acta med scand*, 1948, 132 223

The author studied a number of patients with icterus and attempted to determine the rate of the diazo reactions in the serum by the Deenstra method (*Acta med Scand*, 1948, 132 109) as well as the absorption of bilirubin on the albumin precipitate by the van den Bergh method for indirect bilirubin.

He found that in the first stage of a rapidly changing icterus the rate of the diazo reaction increases predominantly, but it also decreases with the upward or downward fluctuations of the icterus. In the second stage, the diazo reaction increases temporarily when the icterus decreases. During the first stage a rapid diazo reaction is frequently not attended by a stronger adsorption of bilirubin on the albumin precipitate, while during the second stage this phenomenon takes place.

It is also to be noted that the rates of the diazo reaction and of the adsorption of bilirubin on the albumin precipitate may change independently of each other. It is believed that many factors influence the adsorption of bilirubin on the albumin precipitate. The author is unable to explain why the diazo reaction increases temporarily during the

so-called second stage when the icterus decreases. A number of other questions are raised and are left unexplained for the present.

ROBERT TURELL, M D

Injuries to the Bile Ducts P H T THORLAKSON *Canad M Ass J*, 1949, 60 119

Several important concepts may help the surgeon to prevent injury to the bile ducts. Patients with gallstone disease should undergo cholecystectomy early in the course of their disease before extensive pericholecystitis makes the operation technically difficult. Adequate exposure, aided by satisfactory anesthesia and an incision of adequate length is essential. The author prefers a right paramedian muscle-splitting incision, except in large people with a very wide costal angle, in whom a transverse subcostal incision is preferable. Sharp dissection, especially when one encounters adhesions, is recommended.

Indications for exploring the common bile duct are jaundice, or a history of jaundice, palpable stones within the duct, a thickened or dilated duct, a thickened and contracted gall bladder, or doubt concerning the patency of the lumen of the duct. As an additional safeguard against injury one may explore the duct before removing the gall bladder, the presence of the tube in the common duct then facilitates accurate identification of the cystic and hepatic ducts. Probes should be passed up the right and left hepatic ducts and the ampulla should be dilated to 5 mm, never more than 7 to 8 mm.

The author prefers to remove the gall bladder from the cystic duct outward, because when the cystic artery is clamped most of the bleeding is controlled. Anatomical dissection of the cystic duct and artery is important and each should be tied separately.

In some cases when technical difficulties are present a cholecystostomy may be done, especially in a poor risk patient. Rarely, in exceptionally difficult cases, a partial cholecystectomy may be justified.

In the event that free bleeding from the cystic artery occurs, it is a simple matter to compress the hepatic artery in the foramen of Winslow until the bleeding can be accurately controlled.

Anomalous arrangement of the ducts and vessels may confuse the surgeon. The angle which the cystic duct forms with the hepatic duct and the length of the cystic duct are two anatomic details which vary greatly. An accessory bile duct is found in 18 per cent of cases. The right hepatic artery may be double, it may arise from the superior mesenteric artery, or it may lie adjacent to the cystic duct. The cystic artery may arise from the gastroduodenal artery, or from some other branch of the hepatic trunk.

The best time to repair an injury to the common duct is immediately after it is incurred. Therefore the duct should be inspected carefully after the gall bladder is removed and before the cystic duct is ligated. Reconstruction of a severed duct should be

SURGERY OF THE ABDOMEN

effected by end-to-end anastomosis over a tube. The T tube or catheter should never be brought out through the site of injury. It is best not to use too snug a tube since damage to the endothelium of the duct may occur. Structures sutured should not be under tension, and sutures should not penetrate to the lumen of the duct.

The ideal method for the late repair of injuries to the common duct is an end-to-end anastomosis of the cut ends, or, if a stricture is present, resection of the stricture and end-to-end anastomosis. Usually, this is done over a tube which maintains the patency of the duct during the early phases of healing. In the past, rubber tubes have been used for this, but polythene tubes, recently introduced, seem to be better. It is important that the tube be readily removable or easily able to be passed.

When the transpancreatic portion of the duct is not available for the anastomosis, an indirect method must be used. The author prefers choledochoduodenostomy since this is a relatively easy method. If the duodenum cannot be approximated to the duct remnant, a loop of jejunum or a single bowel segment of jejunum must be used. If a loop is used, an enteroanastomosis between the proximal and distal loops at a distance of approximately 18 to 24 inches from the hepatojejunostomy should be performed in order to divert the bowel contents from the site of anastomosis and thus reduce the danger of cholangitis.

In cases in which no extrahepatic remnant of the duct can be identified, a dissection within the liver hilus for the intrahepatic portion of the duct should be made. This may then be anastomosed to a cut end of the jejunum and the continuity of bowel restored according to the Roux en-Y principle. The enteroanastomosis in this case should be made 24 inches from the liver.

Because of the possibility of bile peritonitis, external drainage should be provided following all types of repair of the bile duct.

FREDERICK W. PRESTON, M D

Anastomosis of an External Biliary Fistula into the Gastrointestinal Tract. Report of 6 Cases (A propos de 6 cas de fistule-anastomose pour fistule biliaire d'origine cholédocienne). TINGAUD Rev chir, Par, 1948, 67 353

Patients with external biliary fistulas usually are debilitated because of a long standing illness and the loss of biliary secretions to the outside. Usually at least some degree of liver damage is present. Although an operation designed to re-establish the biliary tract is the ideal treatment for these patients, this often involves a difficult dissection which may prove more than the patient can stand. For such a patient the transplantation of the external biliary fistula into the gastrointestinal tract is a simple and adequate procedure which has received insufficient recognition in the literature.

The authors report 6 cases in which this operation was done. In 3 cases anastomoses of the

fistulas were done after initial exploration revealed that reconstruction of the common duct would be too difficult. In 2 patients a primary anastomosis was done because the patients were in poor condition, and it was necessary to avoid a long operation. In 1 patient a previous operation for reconstruction of the common duct had failed.

The ages of the patients varied from 39 to 70 years. All of the external fistulas were partial, producing intermittent jaundice, and all had followed cholecystectomies. Implantation of the fistula into the stomach was done in 5 patients, and in 1 patient the fistula was anastomosed to the duodenum. In most of the cases the Witzel technique was used, the anastomosis being made over a rubber tube in 2 instances. The results were successful in all except the one in which the patient had the fistuloduodenostomy; this patient died.

The authors believe that the best site for the implantation of the fistula is usually the stomach because of its mobility. In certain cases, in which the duodenum presents readily, it also may be used. The use of the jejunum or ileum for this type of anastomosis is not recommended.

Follow-ups of these patients were made for only a few months. However, the authors cite the experiences of other surgeons, which show that recurring fistulas, recurring strictures, and ascending cholangitis follow this operation no more frequently than they follow anastomosis of the common bile duct to the small intestine over a rubber tube. The chief advantage of anastomosis of the fistula over other reconstructive procedures on the bile ducts is its great simplicity.

FREDERICK W. PRESTON, M D

Technical Conditions of Manometric and Radiologic Control in the Course of Interventions on the Biliary Passages (Conditions techniques du contrôle manométrique et radiologique au cours des interventions sur les voies biliaires). PIERRE MALLET-Guy J internal chir, Brux., 1948, 8 989

Technically, three essential conditions must be fulfilled in the course of interventions on the biliary passages: the asepsis of the surgical intervention should not be endangered by the maneuvers used; the duration of the operation should not be prolonged more than 10 or at most 15 minutes, and this presupposes a perfectly regulated technique without the possibility of false maneuvers, and the data obtained should be easy to read and simple to interpret so that the surgeon may waste as little time as possible in making sure of the diagnosis and drawing the necessary therapeutic conclusions.

The manometric control consists of the registration of a hyperpressure test realized by injecting into the gall bladder or the choledochus a certain amount of tepid water. Sometimes a very small amount suffices to obtain a peak, other times the injection must be repeated to obtain gradually a sufficient increase in the pressure. The roentgenographic control consists in taking two films after the injection of

GYNECOLOGY

Newer Methods in the Management of the Abnormal Cervix GEORGE A. HAHN *Surg Clin N America*, 1948, 28 1401

The author describes the anatomy and physiology of the cervix, and considers the various cervical lesions, erosion, ectropion, leucoplakia, lacerations, and hypertrophy of the cervix.

The symptoms, etiology and clinical picture of chronic cervicitis are discussed and it is believed that the most important step in the treatment of chronic cervicitis is that of determining whether or not beginning cancer is present. If cancer is present, the diagnosis must be made at the earliest possible time so that proper treatment may be carried out. If cancer is not present, elimination of the cervicitis should prove to be an important factor in preventing the first malignant change. Minor lesions are treated by cauterization and coagulation, more extensive lesions are treated by means of the circular biopsy and endocervical resection.

Carcinoma *in situ* is treated by extensive circular cervical biopsy, not by hysterectomy or irradiation.

Cervical polyps, cervical myomas, cervical tuberculosis, and cervical syphilis are briefly discussed.

T. FLOYD BELL, M.D.

Vaginal Cytology in Uterine Cancer (Citologia vaginal no cancro do útero) C. STRECHT RIBEIRO and GIL DA COSTA, JR. *Acta endocr gyn*, 1948, 1 414

This study is based on 12 cases admitted to the radium therapy service of Santo Antonio Hospital of Porto, 1 for observation and 11 with the clinical diagnosis of uterine cancer. Vaginal material for cytologic examination was collected with an Ayre spatula from the entire suspected surface in each patient, spread on slides, fixed immediately in a solution of equal parts of alcohol and ether, and stained with hematin-eosin, Giemsa's stain, and Shorr's stain.

Twelve slides of material collected on 6 alternate days from the patient under observation were negative for cancer cells, but malignant cells were found in the smears from all the other patients and corresponded to forms of grade 4 in 3, grade 3 in 5, grade 2 in 1, and grade 1 in 2 of the patients, while the histologic diagnosis was spinocellular epithelioma in 3, intermediate cell epithelioma in 3, and basocellular epithelioma in 5 of them. Not only were neoplastic cells present on all slides in all the cases of cancer of the uterus but the percentage of altered cells ran from 70 to 90, including the neoplastic cells and the small and varying modifications of the cells normally found in a vaginal smear.

Recognition of cancer cells is relatively easy in menopausal patients and becomes even easier as the ovarian insufficiency increases, since the number of

desquamated epithelial cells becomes proportionately smaller and that of the leucocytes larger. In women with sexual activity the large number of unaltered cells makes the search for neoplastic cells difficult.

The changes observed in nondifferentiated cells vary from those seen in differentiated cells. In the first, the nucleus is predominantly involved and changes occur in its volume, which appears greatly increased in relation to the cytoplasm and varies from cell to cell, or in its configuration (multilobulated or with irregular contour), or in the amount of its chromatin (increase), or in its staining capacity. The differentiated cells show irregular delimitation of the cytoplasm, unequal size, mitotic or amitotic activity, nuclear hyperchromatosis, multilobulation, and monstrous nuclei.

The method is valuable to confirm clinically suspected cancer and should be used to establish a positive diagnosis in cases of incipient malignancy. It constitutes a great aid to biopsy which, however, should always be used to confirm the diagnosis.

RICHARD KEMEL, M.D.

Adenocarcinoma of the Uterus J. MASON HUNDLEY, JR., EVERETT S. DIGGS, and THEODORE KARDASH *Am J Obst*, 1949, 57 52

The procedure of choice in adenocarcinoma of the cervix consists of the investigation of all abnormal vaginal bleeding by thorough curettage to insure an early diagnosis, followed by the intracavity application of radium and, of greatest importance, panhysterectomy and bilateral salpingo oophorectomy.

The five year survival rate of 32 patients who were treated with intracavity radium and panhysterectomy was 84.4 per cent. The five year survival rate of 34 patients who were treated with intracavity radium and roentgen therapy was 20.6 per cent. Twenty-one (64 per cent) of the patients received postoperative roentgen therapy. Postoperative roentgen therapy is believed to be obligatory only when extrauterine metastasis is observed.

No planned treatment by surgery alone was performed. There was no operative mortality and no untoward sequelae during convalescence.

The uteri and adnexa of 67 patients were available for study of the effects of this preoperative intracavitary radiation. Nineteen (28.5 per cent) patients showed no residual malignancy, but residual carcinoma was found in 48, or 71.7 per cent. Extension to the myometrium occurred in 64.5 per cent of patients, and cancer was confined to the endometrium in 35.5 per cent. Tubal involvement was noted in 4 patients and the ovary was affected in 3 patients.

Forty and three tenths per cent of the total number of patients had associated uterine myomas.

The importance of panhysterectomy is stressed.

JOHN R. WOLFF, M.D.

an opaque solution. If the gall bladder route is chosen for the exploration, 20 c.c. of tenebryl are injected and the first film is taken immediately, the second, 3 minutes later. If the cystic or choledochal route is chosen, the two films are again taken with an interval of 3 minutes, but each is preceded by an injection of 10 c.c. of lipiodol. The conclusion is drawn from a comparison of the three standard documents obtained in this manner.

If there is no indication for cholecystectomy under manometric control, the surgeon punctures the gall bladder and, keeping his eyes on the tracing, slowly injects the contents of the syringe (usually, 20 c.c. are needed to form a peak). He observes the return line of the pressure and, when the stylet reaches the vertical line of the peak, he injects a new amount of water and forms systematically four or five curves under the same conditions.

Three results are then possible: (1) in each tracing the stabilization level rises, widely exceeding the level of the normal pressures which are around 18 cm. of water; these are block curves, indicating an obstacle; (2) the pressure does not rise materially and may be stabilized at 0 or below it; hypotony of the biliary passages is probable; and (3) the pressure tends to become stabilized around 18 cm. of water; this is the reaction of a normal gall bladder.

If cholecystectomy is indicated, the cystic duct is dissected and incised transversely over half of its circumference. A probe is used to verify its permeability and, if necessary, the duct is dilated enough to allow the introduction of a special double-jointed cannula, of which the extremity is pushed into the choledochus, the second segment remains in the cystic duct, and the third segment goes under the liver. After removal of some choledochal bile, the manometric system is connected with the cannula. If there is little dilatation, a few cubic centimeters of water suffice to give a peak and the level of

stabilization may be established by superimposition of three or four curves. No spastic reactions of the sphincter of Oddi have been observed.

If choledochotomy is indicated, the calculi are removed and a Pezzer sound of sufficient caliber is introduced into the duct and tied in place. Manometric control is then performed, but it is subject to error because of the possibility of relative blocking of the sound.

The author's experience, based on 850 surgical interventions carried out under these controls, allows him to insist on the efficacy of the method.

RICHARD KEMEL, M.D.

Primary Splenic Neutropenia: A Specific Indication for Splenectomy LOUIS T. PALUMBO *Ann Surg.*, 1949, 129: 131

A case of primary splenic neutropenia is presented as clinically cured by splenectomy and removal of an accessory spleen. The case conforms to the description given by Wiseman and Doan in 1939 and in 1942. The condition in the author's patient resembled Banti's syndrome, Felty's syndrome, subleukemic myeloid leukemia, hyperplastic anemia, malignant neutropenia, or certain types of chronic infection.

The disease occurs as the result of splenic dysfunction caused by selective destructive action of the reticuloendothelial cells of the spleen, and is closely related to congenital hemolytic icterus and essential thrombocytopenic purpura, in which cases the erythrocytes and platelets, respectively, are destroyed.

A definite and accurate diagnosis is dependent upon a complete clinical survey of the patient and a detailed study of the sternal marrow, the circulating blood, and on biopsy of a lymph node.

This disease should be included in the long list of diseases in which splenectomy is definitely indicated.

JOHN R. WOLFF, M.D.

Adenocarcinoma of the Cervix and of the Cervical Stump BAYARD CARTER, WALTER L. THOMAS, and ROY T. PARKER *Am J Obst*, 1949, 57: 37

During the period from 1938 to 1947, a total of 50 cases of adenocarcinoma of the cervix were observed at the Duke University Hospital, Durham, North Carolina. This number represents 3.4 per cent of all cervical carcinomas seen at this clinic. Adenocarcinoma of the cervical stump was found in 11 cases (22%).

In 42 of the 50 cases the carcinomas were in stages 2, 3, or 4 when first observed. The symptoms had been present for an average period of 9 months before the patients were seen so that a delay of 10 months occurred before the diagnosis was made and treatment could be started.

Thirteen (26%) of these patients are living and without evidence of disease, and 6 (12%) have reached the 5 year limit. No deaths occurred as the result of irradiation or surgical treatment.

Eighteen patients received x-ray and radium therapy and of these, 2 are living.

Five patients underwent radical hysterectomy, or radical removal of the cervical stump plus radical lymphadenectomy. In 4 patients, cancer was found in the lymph nodes, in 4 patients, in the cervix, and in 1 patient, in the uterus and vagina. All of these patients have died of cancer.

Similar radical surgical treatment was carried out in 7 cases. In 6 of these the lymph nodes were free of cancer, and in 1 patient the left iliac nodes showed cancer. All 7 patients are alive and without cancer.

In conclusion the author states that the occurrence of 11 cases of adenocarcinoma of the cervical stump, plus the high incidence of squamous cell cancer in cervical stumps strengthens the conviction that panhysterectomy is preferable to supravaginal hysterectomy.

JOHN R. WOLFF, M.D.

Carcinoma of the Cervix JULIETTE BAUD *J Am M Ass*, 1948, 138: 1138

The author reports the results of her study of 105 patients with carcinoma of the cervix (stage I) who were treated from 1929 to 1941 with radium alone, at the Curie Foundation in Paris.

The technique of treatment, and the dosage are given.

Although 2 patients died of sepsis early in this period, sepsis has not developed since 1936, as a result of improvement in hospital conditions. There were few rectal reactions. In one patient, a proved necrotic ulcer developed on the anterior wall of the rectum, which eventually healed.

Of the 105 patients treated, 74 (70.4%) were alive without evidence of disease after an observation period of 5 years. The cases with recurrence are described in detail.

The failures in this series cannot be explained on the basis of dosage delivered, and cannot be attributed to any special anatomicoclinical type of lesion.

The author believes that cure of epithelioma of the cervix uteri, stage I, can be obtained by treatment

with radium alone, as well as with radium plus roentgen rays, and that perhaps the roentgen rays are not necessary. However, rather than undertake such a program too soon they have started to treat a series of patients by performing a Wertheim operation 6 weeks after the intracavitary therapy, thus removing the danger of local recurrence. It also permits study of the effects of radium therapy, and verification of the condition of the pelvic glands.

T. FLOYD BELL, M.D.

The Present-Day Status of Noninvasive Cervical Carcinoma GERALD A. GALVIN and RICHARD W. TELINDE *Am J Obst*, 1949, 57: 15

Since 1940, cervical biopsy has revealed the presence of intraepithelial cancer (carcinoma *in situ*) in 75 cases. In all cases the changes in the surface epithelium were typical. Once this diagnosis was established, a modified Wertheim operation was performed in 67 cases, and conization of the cervix and the application of radium in 7 cases. In the remaining case the lesion was discovered in a cervix amputated during the course of a Manchester procedure. In all cases the entire cervix was available for sectioning. In 55 of these cases microscopic invasive cancer was found, in 10 cases carcinoma *in situ* only was noted, and in the remaining 10, no further abnormality was present.

When a biopsy reveals carcinoma *in situ*, three clinical possibilities may be present. The biopsy may have been taken from the periphery of an advanced cervical cancer, microscopic invasive cancer may be present elsewhere in the cervix, or only carcinoma *in situ* may be present.

A survey of 17 cases of carcinoma *in situ*, followed by spread of the cervical cancer, and 1 case of the authors', led to the conclusion that this type of lesion is a true cancer demanding appropriate treatment. That cervical amputation is not enough has been proved, in 3 cases, by the finding of plugs of carcinomatous tissue well up in the cervical canal.

The authors recommend a modified Wertheim procedure which consists of a total hysterectomy, with removal of 2 cm. of the parametrium on each side of the cervix, plus a fairly wide cuff of vagina. Gland dissection is omitted. An ovary may be saved in younger women. All 67 patients operated upon are living, and without recurrence. One death from cervical carcinoma occurred among the 7 patients who had been treated by irradiation.

All of these lesions were discovered during the routine investigation of patients for gynecologic complaints. None showed any suggestion of gross cervical cancer, although the majority presented some abnormal appearance of the cervix, diagnosed clinically as cervicitis, erosion, eversion, laceration, and leucoplakia. Although most of the patients were asymptomatic, it was learned, on close questioning, that 58 per cent had some type of irregular vaginal bleeding, especially postcoital spotting. Comments on cytologic studies are omitted since the author does not have sufficient data at this time.

The occurrence of basal-cell hyperactivity and its relationship to true carcinoma *in situ* is discussed
JOHN R. WOLFF, M D

Controversial Factors in the Management of Carcinoma of the Cervix ROBERT A. KIMBROUGH, JR., and CRAIG W. MUCKLE. *Surg Clin N America*, 1948, 28 1415

A brief historical survey of the treatment of cervical carcinoma is presented

Although the first radical abdominal hysterectomies were performed by John G. Clark, and independently by Rumpf in 1896, it was Wertheim, in 1898, who popularized the procedure. Victor Bonney became the outstanding successor of Wertheim in continuing the radical surgical approach. The operative mortality and complications were extremely high.

Kelly and Burnham, in 1912, initiated the elective treatment of carcinoma of the cervix with radium. From 1920 until comparatively recently, radiation in various forms was universally accepted as the treatment of choice for all cases of carcinoma of the cervix. The negligible primary mortality, fewer complications, and the high incidence of apparent cures following irradiation made its adoption the treatment of choice.

The technique of radiation therapy with x-rays and radium is outlined.

The results of radium therapy as estimated from present day reports is about 25 per cent, for growths apparently limited to the cervix, it is 75 per cent, for those questionably limited to the cervix, 50 per cent, for those which have invaded the broad ligaments, 20 per cent, and for the advanced cases the 5 year salvage is practically nil. These results are quite comparable to the results obtained by Bonney and Wertheim with the radical operation.

The radical surgical approach has been practiced during the past few years by a few surgeons. Meigs has recently reported in detail his reasons for this radical procedure. He has performed this operation 100 times without an operative death. More than 40 consecutive operations were performed without the development of a single urinary fistula. In 1946 he reported that a 3 year cure rate of 77.7 per cent had been obtained.

At the present time the results of surgical treatment are not significantly better than those following radiation in lesions of similar extent.

T. FLOYD BELL, M D

The Desirable Management of Fundal Carcinoma LEWIS C. SCHEFFEY and WARREN R. LANG. *Surg Clin N America*, 1948, 28 1425

In considering the etiology of the development of fundal carcinoma, the authors review the literature as to the possible influence of unrestrained estrogenic activity. They conclude that there is no indisputable proof that endometrial hyperplasia, per se, is the precursor of adenocarcinoma of the fundus. On the other hand, every worker in the field has probably

seen instances in which clinical observation has given the factual impression that hyperplasia has preceded adenocarcinoma, or has observed an area of hyperplasia accompanying frank cancer of the corpus. These controversial etiological factors should be given due weight when the means of controlling fundal carcinoma are discussed.

Certain physical peculiarities found in patients with fundal carcinoma are enumerated, such as obesity, high incidence of hypertensives, the more than occasional diabetic, and an absence of anemia in the vast majority. Postmenopausal bleeding has, in a goodly proportion of patients, been due to endometrial carcinoma. Four out of 5 patients with fundal cancer are over 50 years of age. Roughly, a third of the patients have never been pregnant and of these, one-half have never married. Women with fundal cancer are more likely to have had menorrhagia in the premenopausal and menopausal epochs.

All patients suspected of having fundal cancer should have curettage, as vaginal smears are only suggestive.

In the premenopausal patients, that comprise 20 per cent of the cases of fundal cancer, the age limit is roughly 40 to 50. In this group, diagnosis is often delayed and mistakes in therapy can happen. Fibroids may be thought to cause the abnormal bleeding. Roentgen therapy may be employed to control the bleeding and the cancer may be overlooked.

There is considerable variation in the histologic picture presented by fundal carcinoma. Although gradation is not always a simple matter, the Jefferson group has tried to simplify it by confining their classification to low, intermediate, and high grades of malignancy.

The clinical grouping of fundal cancer is by no means standardized. The authors follow the grouping of the American College of Surgeons. A better classification may come from the World Health Organization of the United Nations.

The surgical eradication of fundal cancer should consist of total hysterectomy and adnexal removal. In case the disease has invaded the uterus deeply, recurrence may be prompt. With cancer of low malignancy and extension, survival for a long period may occur.

With the advent of radium and x-rays, irradiation came to be utilized almost exclusively in aged or debilitated individuals, and in those handicapped by obesity, diabetes, cardiovascular and renal disease, with striking results in many cases, but before long it became apparent that only arrest of the disease occurred.

The next step was a logical one in combining irradiation and surgery to complement each other. This has resulted in a rational procedure in most gynecologic clinics today. Differences of opinion exist with respect to whether radium or x-ray therapy is superior in the part that irradiation plays. The statistics reported show much better results with preliminary irradiation followed by surgery than by surgery alone.

The methods that are favored in the Jefferson Clinic are presented concisely, in the patient of good operative risk and in the poor risk patient. The best results in their hands has been with irradiation therapy followed by resection, with an encouraging survival rate of 91.2 per cent. T. FLOYD BELL, M.D.

The Role of Surgery in the Treatment of Carcinoma of the Cervix CHARLES D. READ *Am J Obst*, 1948, 56: 1021

Since 1907, when Bonney performed his first radical abdominal hysterectomy for cancer of the cervix, at the Chelsea Hospital for Women in London, England, that group has continued the "all out" surgical attack against this disease. It must be remembered that at the time this approach was started, there was no adequate alternative treatment.

In the late 1920's this operation was largely supplanted by radiotherapy. However, surgery has continued to be used in selected cases.

Although Bonney reported a primary surgical mortality of 14 per cent among the first 500 patients operated upon from 1907 to 1936, this high mortality rate has been remarkably lowered in recent years as the result of a careful selection of patients, improved anesthesia, the use of blood and plasma, the use of penicillin and the sulfonamides, and (not least of all) good nursing. Read and Cook have performed 207 Wertheim operations, with 6 operative deaths (under 3 per cent). About 1 case in every 7 cases are now treated surgically by this group.

The selection of cases for radical operation is confined to radioresistant growths proved either clinically or cytologically, columnar celled (adenocarcinoma) carcinoma of the cervix, stenosis of the vaginal vault prohibiting the accurate placement of radium, the presence of large fibroids or ovarian cysts complicating cervical cancer, salpingitis complicating cervical cancer, refusal of radiation by the patient, and pregnancy complicating cervical cancer.

From 1936 to 1941, radical operations were performed on 54 patients deemed unsuitable for radiation, or who were found to be radioresistant. Thirty-four patients had first stage growths and 20 patients had second stage growths. There were 24 (44.4 per cent) 5 year cures. Three operative deaths (5.5 per cent) occurred in this group.

Studies of the regional glands obtained from the Wertheim operation, lymphadenectomy alone, and autopsy material demonstrated that the degree of lymph gland involvement in patients with stage 1 growths was 20.25 per cent, with stage 2 growths, 30.35 per cent, with stage 3 growths, 40.50 per cent, and with stage 4 growths, 60 per cent. The author believes that the adequate application of radium will definitely cure the majority of local cervical growths, but the effectiveness of deep therapy as a cure of regional gland metastases has not yet been proved.

The technical modifications of the Wertheim operation as it is employed today are described.

With the present state of our knowledge, the routine treatment of election for the average case of

cervical cancer is by radiotherapeutic means, but in certain cases surgical treatment offers the best prospect for the patient. The more extensive use of lymphadenectomy, especially in stage 3 lesions, might improve the results. It is believed that the absolute cure rate in carcinoma of the cervix can be increased by a surgical approach in those cases which prove to be radioresistant, or in which irradiation is not possible. JOHN R. WOLFF, M.D.

Leiomyosarcoma of the Uterus G. HAMILTON DAVIS, JOHN S. HOWE, and WILLARD G. FRENCH *Am J Obst*, 1948, 56: 1048

A recent unusual incidence of four case specimens of leiomyosarcoma of the uterus observed at the pathologic laboratory of the Methodist Hospital, Brooklyn, New York, within a period of 6½ months led to the present study. Sixteen cases were reported in the period from 1917 to 1948 and during that time 2,318 benign leiomyomas were observed, the incidence of sarcoma to benign fibromyoma being 0.69 per cent.

Leiomyosarcomas are classified as "unequivocal" when the gross and microscopic features are definitely malignant, and "low grade" when the histologic pattern is not decisive yet contains malignant characteristics.

All leiomyomas which are unusually soft, friable, or of unusual color should be viewed with suspicion and incised, after removal at the operating table. Immediate consultation with a pathologist should follow and a frozen section should be examined.

The gynecologist should carry out radical procedures in all women over 40 years of age when he encounters grossly typical leiomyomas or those with a history of rapid growth. When the omentum is adherent to leiomyomas, it should be widely excised.

Although recurrence in the retained cervical stump is rare, total hysterectomy with bilateral salpingo-oophorectomy is the procedure of choice.

Of the 16 cases, 11 were adequately followed up. Six patients (54.5 per cent) died of metastases within 2 years and 9 months, 3 patients are living and well, without recurrence, 2 patients have had further operative procedures for recurrences, but to date are living and well, without demonstrable recurrence.

ADNEXAL AND PERIUTERINE CONDITIONS

Concerning 2 Cases of Krukenberg Tumor (Tumor de Krukenberg a propósito de dois casos) ALVARO DE AQUINO SALLES and HILDEFARDO STOLTZ *In Brasil gin*, 1948, 13: 259

Among 4,345 patients admitted to the Gynecologic Clinic of the University of Brazil from 1936 to 1948, there were 14 malignant ovarian tumors (0.37 per cent). Four of these (26.67 per cent) were metastatic secondary to carcinoma of the digestive tract, and 2 of the 4 presented the typical macroscopic aspect of Krukenberg tumors. These 2 cases are described.

MISCELLANEOUS

Torsion of the Organs and of Tumors of the Female Genitalia *Clinical Contribution* (La torsione degli organi e dei tumori dell'apparato genitale femminile Contributo clinico) EMILIO RUGGERI *Ginecologia, Tor, 1948, 14 493*

Seventy cases of torsion are reported. This number represents about 1 per cent of a total of 4,360 patients operated upon at the gynecological clinic at Parma, Italy, in the period from January, 1939 to March, 1946. The material comprised 58 cases of torsion of ovarian and parovarian tumors, 4 of subserous, pedunculated fibroids of the uterus, 5 of the tube, and 3 of the uterus itself. Nearly all these patients with torsion were engaged in work requiring physical activity and most of them were in the child-bearing age, however, there was no evident relationship to the number of children they had borne. Among the ovarian and parovarian tumors torsion was about twice as frequent on the left side, which gave some support to the role played by the sigmoid colon in the etiology of this condition, there was a disproportionate number of torsions among the dermoid cysts (heavier tumors), but there was no marked effect from the size of these growths. The more irregularly shaped masses seemed more prone to twist. There was no evidence to the effect that the length of the pedicle was of significance.

The diagnosis is apt to be difficult and in some cases is practically impossible. The leucocyte count is apt to be low in these cases of torsion, especially when they come to operation early, however, when the condition is accompanied by appendicitis the former may not be distinguishable. This may be true also in torsion of a tumor of the pelvis combined with extrauterine pregnancy. The author's clinic is starting to resort to peritoneoscopy in some of the acute abdominal cases and this may solve some of the diagnostic problems which are involved.

The treatment is always urgent surgery. The suprapubic route is preferable, both because of the visual control of the procedures to be chosen and because of the opportunity to use intraperitoneal chemotherapy (sulfonamides). Chemotherapy, thus applied, is regarded in this clinic not only as widening surgical indications but also as improving the prognosis.

In this entire material there was only 1 death and this could not have had more than a casual connection (pachymeningitis) with the original condition.

In 1 of the 4 pregnant patients the uterus was removed because of multiple fibroids and toxicity, in the other 3 patients the tumor was removed with continuance of the pregnancy to term.

JOHN W. BRENNAN, M.D.

The first is remarkable because of the extraordinary survival of the patient, who had had a gastroenteroanastomosis for probable anterior gastric tumor $8\frac{1}{2}$ years previously, and a right oophorectomy for a solid tumor 4 years and 3 months previously. This history and the presence of another large genital tumor, with ascites, metrorrhagia, rapid weight loss, and asthenia, led to the diagnosis of Krukenberg tumor. As a preliminary step before operation, a celioscopy was performed which, as a diagnostic aid, may be of great value since it allows direct visualization and endoscopic color photography of the tumor, biopsy, and the aseptic collection of peritoneal fluid for bacteriologic, chemical, and cytologic examination. In this case about 8 liters of ascitic fluid were removed, it was slightly bloody and contained a large amount of mucin and neoplastic cells having the typical signet ring aspect of Krukenberg tumor cells. A pneumoperitoneum was produced and revealed the presence of a large friable tumor with irregular surface, which occupied most of the small pelvis and whose point of attachment could not be determined. Total hysterectomy with left salpingo-oophorectomy was performed. The patient died 3 weeks after the operation.

The second patient had been operated upon for malignant tumor of the jejunum 2 years previously and presented a large, rapidly growing tumor in the pelvis, apparently of ovarian origin. She was in satisfactory general condition. At laparotomy the tumor was found to be inoperable and the abdomen was closed after material for examination had been taken. The diagnosis was bilateral ovarian Krukenberg tumor with infiltration of the small intestine, ileopelvic colon, and epiploon. Deep roentgen therapy was instituted, but death in cachexia occurred 11 months later.

About 20 cases of Krukenberg tumor have been reported in Brazil, most of them among multiparas from 25 to 54 years old. All of the tumors were bilateral and secondary, and only 1 patient survived more than 1 year. Although at present the consensus is that this tumor is always metastatic and secondary to a primary gastroenterogenous, mammary, vesicular, pancreatic, hepatic, or suprarenal carcinoma, the possibility of its being primary in the ovary cannot be excluded. Many theories have been advanced to explain the special predisposition of the ovary to develop metastases. Changes in the surface tension and in the pH may be contributing factors.

With regard to the surgical treatment, the question has been raised as to the convenience of preserving the uterus in order to allow the use of radium tubes as a complementary method to deep roentgen therapy in the postoperative period. The prognosis is always unfavorable because of the metastases which appear by the lymphatic route or by implantation after the primary tumor has been removed.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Volvulus of the Sigmoid Colon in the Course of a Pregnancy of 7 Months (Volvolo del colon sigmoideo nel corso de una gravidanza al settimo mese)
GIUSEPPE BRACCO *Ginecologia*, Tor., 1948, 14 544

The patient, a housewife 44 years of age, had had one natural labor 3 years previously and was now 7 months' pregnant. She had suffered in youth from dyspepsia and enterocolitis. For several weeks now she had been suffering from attacks of abdominal pain, especially pronounced in the left iliac fossa, and of obstinate obstipation. These attacks would clear up, but finally, however, paroxysmal pains, progressive meteorism, dilatation of the stomach, and complete retention of the feces and gas developed at night. Roentgenologic examination with an opaque enema disclosed, in addition, the exact location and character of the twisted sigmoid.

At laparotomy the sigmoid at the indicated point was found to be twisted about itself for 360 degrees and exhibited the usual signs of tissue necrosis. Since the patient's general condition was still not grave it was decided to resect the involved loop of intestine (about 60 cm of gut) with end-to-end anastomosis. The pregnancy was left undisturbed. At first the convalescence was undisturbed and gas and feces began to pass, however, on the fourth day after operation there was a sudden change for the worse, with intense meteorism, hiccoughs, dry tongue, a temperature of 37.2°C, pulse from 90 to 100, and retention of gas and feces. After 2 days of this the patient went into labor and gave birth to a premature infant (1,870 gm) which died 2 days later. After this childbirth the patient's condition improved rapidly and she was discharged 10 days later (18 days after operation) in good condition.

At the operation the mesosigmoid was found thickened and retracted and this is believed to explain the tendency of the long sigmoid loop to twist on itself. The sudden obstipation coincident with the start of labor is well known and is the reason that so many authors have advocated artificial interruption of the pregnancy preceding, or following, any operative approach to the volvulus itself. However, the patient in the author's report here given was in excellent general condition and there was no evidence of impending labor at the time of operation, the case is therefore thought to help establish an indication for noninterference with the labor in such cases.

JOHN W BRENNAN, M D

Purpura Hemorrhagica as a Complication of Pregnancy J A CHALMERS *Brit M J*, 1948, 2 1020

Purpura hemorrhagica is a rare complication of pregnancy. The author reviews 63 cases recorded in the literature, and a further case is now added. In the present case the purpura was acute and transient,

and labor was unattended by any complication. Treatment should be directed to restoring the blood picture to normal before the onset of labor. If this is impossible, special measures for the control of postpartum hemorrhage may be necessary. The prognosis in the acute cases is good, but there is grave danger of maternal death in the chronic cases. The fetus is commonly involved, and may die of hemorrhage or of prematurity associated with the early onset of labor in a considerable proportion of these cases.

CHARLES BARON, M D

Corpus Luteum Excision During Pregnancy and Its Effect on the Production of Progesterone (Lu tectomia en el embarazo y su efecto sobre la producción de progesterona) JOSÉ BOTELLA LLUSIÀ and MANUEL LADRÓN DE CEGAMA *Acta endocr gyn*, 1948, 1 408

In 1946 the authors published 3 cases in which the gravidic corpus luteum was removed without producing abortion, one of the patients had been pregnant for 45 days and one was operated upon 8 days after the fecundating coitus. In this article 2 additional cases are described.

The first woman was pregnant for 2 months and had a left ovarian cyst, the size of a mandarin, with the corpus luteum on its proximal pole. The second was also pregnant for 2 months and had a bilobular twisted right ovarian cyst, the size of an orange, with the corpus luteum in some normal ovarian tissue which persisted between the two lobules of the cyst. No signs of luteinization were found in the other ovary of either patient. The involved ovaries were removed and the pregnancies continued to run their normal course.

The urinary pregnandiol was determined for several days following the operation in both patients and was found to remain constant and within the limits normal for pregnancy, despite the absolutely certain removal of the gravidic corpus luteum which has been accepted as the only source of progesterone, and therefore of pregnandiol, or at least as its principal source during pregnancy. It must consequently be admitted that progesterone can be produced outside of the ovary in quantities sufficient to maintain pregnancy and that this vicarious production takes place from the beginning of the pregnancy. The conclusion to be drawn is that the corpus luteum is not needed as a source of lutein hormone during pregnancy.

This progesterone may come from two sources: one is the placenta which, according to experiments of Seegar and his coworkers with cultures of young chorionic tissue, acquires very early the property of producing lutein hormone, the other is the suprarenal cortex, of which the progesterone content has been determined by Engelhart and Beall, and its relations with the corpus luteum as well as its hypertrophy during pregnancy have been amply described.

by the present authors in another article. As far as they know, this is the first note to appear in the literature concerning the behavior of the urinary pregnandiol after resection of the corpus luteum during pregnancy.

RICHARD KEMEL, M D

The Diagnosis of the Sagittal Suture, the Chin, and the Ear in the Posterior Occiput to Brow Presentations (Die Pfeilnaht-, Kinn- und Ohrdiagnose bei der hinteren Hinterhaupts bzw. Vorderhaupts-lage) ROLF SCHMIDEMANN *Geburtsh. & Frauenh.*, 1948, 8 759

The author bases his opinions on a study of 281 posterior cephalic presentations over a period of 20 years.

He believes there are three important diagnostic procedures useful in posterior occiput, vertex, and brow presentations: determination of the sagittal suture (often by rectal examination alone), the palpation of the chin, and the palpation of the ears (by vaginal examination).

By feeling the sagittal suture one can detect the time of internal rotation. Location of the chin immediately identifies the whereabouts of the anterior and thence the posterior fontanel. The posterior border of the ear necessarily directs itself toward the occiput.

Although these observations are elementary, they are sufficiently important for re-emphasis.

WARREN R. LANG, M D

Modern Indications for Cesarean Section NEWLIN F. PAXSON *Surg. Clin. N. America*, 1948, 28 1487

The chief dangers of cesarean section are hemorrhage and infection, specifically peritonitis. These dangers have been controlled by improved surgical techniques, modern anesthesiology, blood transfusion, sulfonamides, antibiotics and oxytocics, so that the risk of cesarean section has been reduced to that of vaginal delivery of a few decades ago. Now that cesarean section may be used with greater impunity, the indications have been broadened to include many conditions that formerly were forbidden because of the great risk. This means the saving from death or damage of more mothers and babies. However, a new risk has been added. Due to a false sense of security on the part of the obstetrician, cesarean section is sometimes performed as a substitute for a less risky delivery through the birth canal. It must not be forgotten that the risk in cesarean section is five to ten times greater than that in vaginal deliveries. Dystocia, hemorrhage, and similar major complications offer the chief indications for cesarean section, which should be decided on the following evaluation of risks.

1 If the danger to mother or child by vaginal delivery is less, cesarean section is contraindicated.

2 If the danger to mother or child by vaginal delivery is equal to that by cesarean section, then the type of delivery selected will depend on the skill of the obstetrician. Some of the problems which arise in this group are now included in the modern

indications for cesarean section where formerly vaginal delivery was indicated.

3 If the danger to mother or child is greater by vaginal delivery, then cesarean section is indicated.

Fetal-pelvic disproportion at the inlet may be recognized before the onset of labor by the physical signs of abnormal presentation, high presenting part, premature rupture of the membranes, and pelvic mensuration. The following criteria should be used in evaluation of contracted pelvis with disproportion at the inlet: shape of the inlet, anteroposterior diameter (true conjugate), transverse diameter, and size of the fetus, particularly of the head.

The best method of individualizing fetus and pelvis by physical examination was first described by Muller, and later improved by Hillis, and consists of placing a finger in the rectum or vagina while the other hand (or an assistant) presses on the fundus. In this way the head is brought down to engagement, or below, if there is no disproportion. If disproportion is present it cannot be engaged. (Engagement is defined as being present when the head covers three-fourths of the symphysis pubis, two-thirds of the sacrum, and the most dependent portion of the skull, not scalp, reaches an imaginary line drawn between the ischial spines. This is known as "station 0"). In flat pelvis the head must descend 1 cm lower before it is engaged. When disproportion at the inlet has been discovered during pregnancy, by physical signs and pelvimetry, then complete roentgen studies should be made and the case evaluated. If disproportion is extreme, elective cesarean section should be selected; if moderate, the patient should be given a test of labor. A satisfactory method of evaluating the degree of disproportion is found again in the Muller-Hillis maneuver and the author uses the following standards:

1 Severe disproportion exists if, in the presence of a well developed lower uterine segment, the head cannot be brought lower than 3 cm short of engagement (station -3). An elective cesarean section is indicated and other common signs of disproportion usually are present.

2 Moderate disproportion exists if the head can be brought lower than 3 cm short of engagement but still does not engage (between station -3 and station 0). A test of labor is then indicated. It is in this group that disproportion is often missed, particularly if the head can be brought down to station -1. Too often it is interpreted as reaching station 0, or even +1 where a little more care and skill in making the examination would show the true condition.

At present there is no clearly defined test of labor other than the well known anatomicophysiology test and this is usually too prolonged to be considered safe, a proper decision can be made long before such a severe test is completed. The most important factors involved in a test of labor are (1) the shape and size of the pelvis, (2) the size of the baby and degree of molding, and (3) the strength and frequency of uterine contractions. These factors involve so many variables that there are no stan-

Too often it is interpreted as reaching station 0, or even +1 where a little more care and skill in making the examination would show the true condition. At present there is no clearly defined test of labor other than the well known anatomicophysiological test and this is usually too prolonged to be considered safe, a proper decision can be made long before such a severe test is completed. The most important factors involved in a test of labor are (1) the shape and size of the pelvis, (2) the size of the baby and degree of molding, and (3) the strength and frequency of uterine contractions. These factors involve so many variables that there are no stan-

dards used other than an arbitrary number of hours selected by each individual obstetrician. The impatient and the surgically minded prefer a short time, the more patient and conservative ones prefer a longer time. The author attempts to solve this problem by use of the following standards:

After labor is established, with a good uterine contraction lasting longer than 30 seconds, at 5 minute intervals or oftener, and showing some shortening and effacement of the cervix, a Muller-Hillis maneuver is done every 3 or 4 hours. The shorter interval is used when the labor is more active and the longer, if less active. If the test is going to succeed it will be found that with each maneuver the head can be brought to a slightly lower level, and the test may be continued. However, if at the second of two successive maneuvers progress is stationary and the head cannot be brought to a lower level than at the previous examination, the test should be considered a failure and the baby delivered by cesarean section without further delay. Thus, a decision can be reached before the complete dilatation and the 2 hours of labor required by the anatomicophysiology test. In fact, the success of the test is dependent on the fact that in normal labor the head will descend through the pelvic inlet before the cervix is fully dilated.

Contraction of the midpelvis is occasionally seen, usually in android and anthropoid pelvises, and is first recognized during the physical examination by the prominence of the ischial spines. As soon as this is discovered the sacrospinous notch should be palpated and its width in fingerbreadths noted. A test of labor may be permitted in midplane contraction since the head is not too low at this level to be reached by abdominal section. Such tests should not last a long time but if progress is definitely arrested at the ischial spines cesarean section should follow promptly.

A contracted outlet, severe enough to require cesarean section, is quite rare but must be recognized early. Once the descending head has reached the narrow outlet and obstruction develops, a destructive operation is the proper treatment, for, with the narrow intertuberous transverse diameter and the short posterior segment due to the shallow sacrum, the baby will be badly damaged or killed if forceps are attempted.

Stenosis of the cervix is commonly acquired rather than congenital, and usually requires cesarean section. It follows one of the varieties of surgical treatment to the cervix, since any procedure that leads to extensive scar tissue will cause rigidity.

If the patient has reached term and a tumor takes up enough space in the pelvic inlet to cause dystocia, she should be delivered by cesarean section.

Patients with congenital anomalies require cesarean section whenever they cause stenosis and obstruction, otherwise they do not interfere with labor. One condition that should be watched is the double uterus. If the nonpregnant uterus becomes incarcerated in front of the fetus, it will act the same as a blocking tumor, and cesarean section is indicated.

Since spastic contraction rings can be diagnosed positively only by a hand in the uterus, they are not often recognized. Most of such manifestations of local tetany respond to antispasmodics such as demerol and scopolamine in combination, but if a permanent constriction ring is present only cesarean section will deliver the baby.

Placenta previa and premature separation of the placenta have much in common as far as indications for cesarean section are concerned. The two chief points for consideration are the amount of bleeding and the degree of cervical dilatation. Active bleeding requires prompt treatment and the quickest way to control such hemorrhage is to deliver the baby and placenta. If the cervix is incompletely dilated, preliminary operations to complete dilatation only add further trauma and hemorrhage, making a bad case worse. Cesarean section solves the problem quickly and efficiently. If the bleeding is only slight, more conservative measures may be used, or if the cervix is fully dilated, forceps or even version are indicated. The big danger in cases of hemorrhage is active bleeding in the presence of an incompletely dilated cervix, and in such a situation cesarean section should be the first treatment considered. While in placenta previa, cesarean section is usually indicated in the centralis and partialis varieties, the marginal type may be treated by more conservative methods such as puncture of membranes, Braxton Hicks version, Willett's traction forceps, and others. In premature separation, particularly abruptio placenta, with a long cervix, cesarean section is to be chosen. In the milder types the accepted conservative methods may be used, especially if the baby is dead, but if there is a chance to obtain a living child cesarean section offers the best hope and the burden of proof of correct judgment lies on him who decides otherwise.

Cesarean section is indicated in heart disease only when there is a prospect of obstruction due to disproportion or to dystocia from other causes.

Labor in thyrotoxicosis and pulmonary tuberculosis should be treated on the same principles as heart disease. Diabetes may require cesarean section in those cases in which the chorionic gonadotropin levels persist above normal, in spite of adequate estrogen and progestin therapy, with the consequent danger of an oversize, over-term, dead fetus. Here an elective cesarean section is indicated about 2 weeks before the calculated date, provided palpation and abdominal mensuration show the fetus is large enough to be viable. Sterilization per se is not an indication for cesarean section.

There are a number of fetal indications for cesarean section. Abnormal presentation and position is one of the signs of pelvic inlet contraction before the onset of labor, as stated earlier, but this does not mean that disproportion is the only cause. In general, abnormal presentation in a contracted pelvis is an indication for cesarean section, but when the contraction is only slight and the fetus small, vaginal delivery is the better choice. Transverse presenta-

tions are particularly dangerous and a primigravida with dry labor should be sectioned even if the pelvis is normal

Breech presentations in a primigravida should be studied carefully, if the pelvis is contracted more than a slight degree, elective cesarean section is indicated. Elderly primigravidas approaching 40 years of age should be treated in the same way even if the pelvis is normal since the baby has a high priority, and it is impossible to predict how the after-coming head will descend through the pelvis. Of course, greater pelvic contractions require cesarean section unless it has been proved that a large sized baby can be delivered safely through the birth canal by previous successful labors, for there is no way of conducting a test of labor in either breech or transverse presentations. The correct decision must be made, at the latest, before the first stage is completed.

Fetal monsters commonly present abnormally and can be recognized in most instances by roentgen studies. The most treacherous cases are hydrocephalus with breech presentation and soft tissue tumors that do not cause a shadow on x ray film. In general, monsters are not an indication for cesarean section but should be treated by destructive operation after the cervix is fully dilated. Rarely cesarean section must be done when a vaginal delivery is impossible.

Marked variation of the fetal heart rate during labor is one of the newer indications for cesarean section and this indication should be used with caution. It is usually a sign of cord complications, such as forelying cord, occult prolapse of the cord, tight loops and coils of a long cord, or an unduly short cord. This is not an indication for cesarean section before the onset of labor unless the fetal heart rate shows very marked change of rate. The best example of such indication is seen in a primigravida with very little cervical dilatation and marked variations of the fetal heart rate between pains.

The elderly primigravida of 40 years or over usually should be delivered by elective cesarean section because of the high priority value of the baby. In most cases this is the woman's only chance to have a baby, and with the difficulties of labor likely to be encountered it is best to offer the fetus every opportunity for safe delivery. Again this is a generalization and there are occasional exceptions, for each case should be decided on its own merits. Last of all, cesarean section in a dying mother or immediately postmortem is a fetal indication that should not be forgotten.

The dictum of "once a cesarean section always a cesarean section" is not necessarily true, for with careful study, observation and skill, certain patients who previously have undergone cesarean section may be delivered successfully through the birth canal. Elective cesarean section is required in all cases in which the previous indication was contracted pelvis, likewise if wound healing at the former section was complicated by endometritis and uterine infection, since there is danger of rupture of the uterine

scar during the next labor. In other words, cesarean section is indicated in a succeeding labor if there is danger of obstruction, dystocia, or rupture of the uterine scar due to poor wound healing. Delivery through the vagina may be considered and attempted if the previous section was for hemorrhage, toxemia, or some similar indication in which the problem of dystocia was not involved and convalescence was uncomplicated by infection.

There is no substitute for thorough study, careful observation, and skill. CHARLES BARON, M D

LABOR AND ITS COMPLICATIONS

Fetal Mortality in Breech Deliveries WARD F SEELEY *Am J Obst*, 1949, 57 113

A survey of 1240 breech deliveries in the two 5-year periods from 1932 to 1936 and from 1942 to 1946 at the Harper Hospital and at the Herman Kiefer Hospital, Detroit, Michigan, shows that even in expert hands the fetal risk in breech presentation is greater than in vertex presentation.

The very high gross fetal death rate often attributed to the breech position is, to a great extent, due to the inclusion of very premature infants who would have little chance of survival with any position, of those severely malformed, and of those already dead on admission.

There is no increased risk for viable prematures when presenting by breech, yet birth weight is an important factor in fetal death. Babies of medium weight have the best chance of survival.

The frank breech position does not seem to increase the fetal risk. The length of labor is not an important factor.

Babies of elderly primiparas with breech presentation have a higher mortality if they are delivered vaginally.

Prolapsed cord is a definite added hazard as it occurs six times more frequently in breech than in vertex presentations.

The maternal risk is not increased, and mortality is due to associated conditions not due to the breech presentation. A slight increase in morbidity follows perineal injury, which can be prevented by episiotomy.

Prophylactic version deserves more universal consideration. Elderly primiparas, patients with pelvic contraction, even though of mild degree, primiparas with large babies, and cases with various combinations of these conditions deserve careful consideration of delivery by cesarean section. Better care should aid in reducing the mortality among fetuses developed sufficiently for extrauterine life.

The importance of the skill of the attendant is well exemplified by the survey. From 1932 to 1936, when the deliveries were conducted by internes and residents, the stillbirth and neonatal mortality for full term infants was 6.5 per cent. From 1942 to 1946, when 95 per cent of the deliveries were by skilled attending men, this mortality was 3.5 per cent.

JOHN R. WOLFF, M D

PUERPERIUM AND ITS COMPLICATIONS

Several Indications for Infiltration of the Renal Pedicle During Pregnancy and the Puerperium (De quelques indications de l'infiltration du pédicule rénal pendant l'état gravidopuerpéral) RIVILERE, MAHON, CHASTRUSSE, and SOUMIREU *Gyn obst*, Par, 1948, 47 646

It has been determined experimentally that section of the renal pedicle brings about vasodilatation of the renal arteries and diuresis. This same effect can be induced by infiltration of the renal pedicle with novocain. It has been noted clinically that novocain infiltration of the renal pedicle employed in the treatment of nephritic colic also abolished the spasm of the ureter and pelvis, bringing about a vasodilatation and a polyuria, and a secondary fall in the blood pressure. This effect was proportional to the extent to which nervous reflex mechanisms were involved in the anuria.

During the pregnant and puerperal states anuria or oliguria is not rare, it is often seen in eclampsia, pre-eclampsia, retroplacental hemorrhage, pyelonephritis, and in all of these cases vascular spasm is of great importance. The authors believe that this is a functional spasm which can be relieved by novocain infiltration of the renal pedicles (the technique is not described). These effects cannot be so dramatically shown in the woman who has underlying renal disease.

Infiltration of the pedicles can also induce diuresis in cases of postabortion nephritis. Cases of the latter are described in which the abortion had been attempted by the use of certain poisons and by the intrauterine instillation of soapy water. Typically, an acute nephritis with anuria was produced, the treatment for which consisted of penicillin and novocain infiltration of the renal pedicles, if the latter procedure was not successful, immediate decapsulation of the kidneys was done. One per cent novocain was employed, 25 c c in each pedicle, in a few cases decapsulation was carried out.

Fourteen cases were reported: 5 cases of eclampsia with anuria, all responding favorably to infiltration by diuresis, 2 cases of severe toxemia, both ending fatally in spite of therapy which included infiltration, 5 cases of postabortive nephritis following the use of soapy water in the uterine cavity as an abortifacient—diuresis followed infiltration in 3 of these cases, 2 cases of toxic nephritis with anuria following the ingestion of poisonous abortifacients—diuresis followed infiltration in 1 case, while the other ended fatally.

Infiltration of the renal pedicles deserves merit in all cases of anuria and oliguria observed during the pregnant and puerperal state. Failure of this procedure to induce diuresis is an indication for renal decapsulation for it signifies that the functional state is passed and that the obstruction has become mechanical. In the cases of postabortive nephritis this is indicated especially in the prevention of this renal complication of abortion, caused by the

methods described, early infiltration can be life saving.
PHILIP B. CHASE, M.D.

Indications for Renal Decapsulation During the Pregnant and Puerperal State (Les indications de la décapsulation rénale au cours de l'état gravidopuerpéral) R. MAHON and H. DAVY *Gyn obst*, Par, 1948, 47 653

In the pregnant and puerperal state, when anuria and azotemia appear and are resistant both to medical treatment and to the infiltration of the renal pedicles with novocain, early decapsulation of the kidneys affords the best chance of initiating diuresis. Renal decapsulation in the pregnant woman is not a new operation, having been performed first in the United States in 1903 and in France in 1905. The old indication was a persistent anuria 24 hours after delivery of the fetus, but in recent years this procedure has only been attempted in the anuria following criminal abortion. Decapsulation does not have an excellent reputation, and was formerly used only as a last resort. However, it has its merits as a procedure to be employed in a definite anuria which does not respond to other therapeutic measures and which is complicated by a progressive azotemia. This train of events usually arises in the following situations:

1. In criminal abortions, following either the ingestion of poisons or the intrauterine injection of soapy water, accompanied in the latter case by gas bacillus (*Clostridium welchii*) infection.
2. In certain forms of gravidotoxic pyelonephritis.
3. After certain eclamptic states.

The anuria following attempted criminal abortion by the taking of poisonous abortifacients is the most serious of the various symptoms which must be treated. Extreme congestion and cytotoxicity of the kidney parenchyma and tubules are noted pathologically, the result of a slowly developing process which can be checked by decapsulation.

"Soap nephritis," a form of toxic nephritis, can follow the intrauterine injection of soapy water, its most serious complication is anuria and secondary azotemia which is treated most successfully by renal decapsulation. This should be accompanied by penicillin therapy and other such measures as the intravenous injection of fluids and novocain infiltration of the renal pedicles. There should not be more than a 24 hour delay; then decapsulation should be done, first on one kidney and then on the other 2 or 3 days later.

Clostridium welchii bacillus can produce a severe generalized toxemia of which nephritis with anuria and secondary azotemia is the most serious manifestation. Although penicillin may check the initial infection, the anuria and azotemia may persist, and only decapsulation can initiate diuresis. Even when hysterectomy is indicated because of gangrene, decapsulation should be carried out.

In the anuria of gravidotoxic pyelonephritis, renal decapsulation has its place in treatment along with the intravenous injection of fluids and novocain infil-

tration of the renal pedicles Two cases of gravidotoxic pyelonephritis, one a chronic nephritis aggravated by pregnancy, the other an acute nephritis appearing in the course of a pregnancy, are reported. All of the symptoms of eclampsia disappeared following delivery except the anuria and azotemia which responded only to decapsulation of both kidneys. At operation renal biopsies were taken and disclosed a nephritis with extensive tubular epithelial destruction and cytoplasmic vacuolization, which left no doubt as to the severe derangement of the renal physiology. It is concluded that in all cases of post-eclamptic anuria, decapsulation of the kidneys should be done when medical management fails.

In anuria occurring late in pregnancy it is advisable to empty the uterus before term, delivery of the fetus frequently bringing about renal decongestion. However, if it occurs early in pregnancy before the fetus is viable, renal decapsulation should be carried out and the integrity of the pregnancy maintained if possible.

NEWBORN

Umbilical Healing and Infection (Ueber Nabelheilung und Nabelinfektion) WILHELM H. THIELE *Geburtsh. & Frauenh.*, 1948, 8: 774

The author calls attention to the dangers which appear after the dried remnant of the umbilical cord has sloughed off. In view of the relatively long time it takes for complete epithelization to occur and the presence of pathogenic bacteria, the equilibrium between bacterial virulence and body defense can easily break down.

The resulting infection may take various forms. There may ensue an acute peritonitis or fulminating

sepsis. What seems to be merely a nutritional disturbance may also develop.

With signs of poor nutrition, especially in the breast-fed infants, one must consider umbilical infection. The diagnosis is made by inspection. Probing for pus may be dangerous. The recommended treatment of the sloughing cord is the so-called "dry method" of management.

WARREN R. LANG, M.D.

MISCELLANEOUS

Kidney Function in the Fetus SAMUEL T. THIERSTEIN, FRED D. COLEMAN, and FRANK H. TANNER *Am. J. Obst.*, 1948, 56: 1178

In the present article the authors state that since the kidneys are functioning at birth, one frequently observes urination a very short time after birth. Knowing that the infant is born with a full bladder, one can speculate on how frequently the fetus urinates during the last months of fetal life and in what quantities urine is secreted.

A case report is presented of an infant delivered with an enormously distended bladder containing 4,200 c.c. of urine. The extreme abdominal enlargement prevented delivery of the baby until the bladder was incised and the fluid evacuated. The kidneys were normal except for secondary changes due to secreting against pressure. The urethra was patent, and the cause of the obstruction, or lack of elimination of the urine from the bladder, can only be surmised.

The volume of urine found in the bladder of this infant may be a clue to the approximate amount secreted by all fetuses during the last months of intrauterine life.

JOHN R. WOLFF, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY, AND URETER

Adrenalectomy in the Treatment of Arteritis (La place de la surrénalectomie dans le traitement des artérites) LUCIEN LEGER, A MATHIVAT, and S TCHÉKOFF *Presse méd*, 1948, 56 898

Arteritis occurring in young and middle-aged patients can sometimes best be treated by unilateral adrenalectomy. This is true particularly in patients in whom medical treatment and lumbar sympathectomy have failed.

Experimental evidence that hyperadrenalism produces peripheral arterial lesions has been obtained by Leriche and others who transplanted adrenal glands subcutaneously in rabbits every 4 or 5 days. These animals developed peripheral arterial thromboses. Leriche observed gangrene develop in the paw of one animal after the fourth transplant.

The operation of adrenalectomy in the treatment of arteritis was introduced by Oppel in 1917, and later revived by Leriche and his school. Many modern surgeons have abandoned it because they thought that the results obtained were not sufficiently good to warrant such an extensive operation. Many failures in the past are attributable to lack of understanding of the indications for the operation.

The authors have used this operation in the treatment of 25 patients since 1943 without an operative death. These patients suffered from an occlusive type of peripheral arteritis of the lower extremities. The disease is of unknown etiology, it affects younger patients, and it was particularly frequent after the recent World War. Among the 25 patients, none had diabetes, syphilis, or Buerger's disease.

A total removal of one adrenal gland is done through a lumbar approach with removal of the twelfth rib. Usually the left adrenal is resected, sometimes the right. The lumbar sympathetic chain is not disturbed.

Among the 13 cases which have been followed postoperatively for 2 years or more, the results in 8 were classified as good, in 2 as fair, and in 3 as failures. However, even in patients who did not present a satisfactory result, there was no further progression of the pathologic process, and no patients required amputations of the major extremities.

Of the 25 adrenal glands removed none was normal morphologically. The most common gross lesion was hyperplasia of the adrenal cortex, resembling that sometimes seen in patients with hypertension. Microscopic changes included thickening of the capsule, hyalin changes and sclerosis of the capsular vessels, sclerosis of the zona glomerulosa, hyperplasia of the zona fasciculata, hyperplasia of the zona reticulosa in 7 cases and atrophy in 5 cases, and islands of lymphocytes in the zona fasciculata.

Although the authors have obtained good results in 2 patients over 60 years of age, they emphasize

that it is in those below 50 in whom the operation is indicated. The arteries must still show ability to constrict, and gangrenous lesions, if present, must not be too far advanced.

FREDERICK W PRESTON, M D

Megaloureter. A Report of 2 Cases J H CARVER *Brit J Surg*, 1948, 36 168

Two patients with unilateral hydronephrosis and hydroureter are reported. Nephroureterectomy was performed in both cases. The specimens presented marked hypertrophy of the muscularis, normal ureteral orifices, and little or no infection. The etiology of megaloureter is discussed. The author prefers to attribute his 2 cases to neuromuscular imbalance at the ureterovesical junction and offers them in support of Hurst's theory of achalasia.

ORMOND S CULP, M D

Diverticulum of the Ureter (Divertículo del uréter) PEDRO MOREYRA BERMAN and ALBERTO HALAC *Bol Soc cir Cordoba*, 1948, 9 123

Diverticulum of the ureter is very rare. Diagnosis is made only from urographic studies. The case reported by the authors was that of an otherwise healthy man of 35 years who complained of left lumbar pain. Cystoscopy was of no value but ureteral catheterization revealed deficient elimination of the left kidney and x-ray films of the lower third of the left ureter demonstrated a large saccular diverticulum. The condition is considered embryologic in origin, the abnormality probably arising from the wolffian canal.

Treatment depends upon the location of the diverticulum. The indwelling catheter should be used when surgery is done and should remain *in situ* until healing is completed, regardless of whether the diverticular sac is excised, ligated, or transplanted into the bladder. When the kidney is diseased uretero-nephrectomy may be indicated. The authors' case was treated by simple ureteral catheterization and dilatation of the orifice of the diverticulum until all subjective symptoms disappeared. The prognosis depends on the circumstances complicating the findings.

STEPHEN A ZIEMAN, M D

Implantation of Secondaries from a Renal Carcinoma (Hypernephroma) within the Ureteral Lumen JAS B MACALPINE *Brit J Surg*, 1948, 36 164

Five years after a left nephrectomy was performed for "hypernephroma," a 44 year old female had recurrence of hematuria which came from the ureteral stump. Ureterectomy revealed two tumors within the lumen, both of which were histologically similar to the cortical neoplasm.

Thirteen years after the nephrectomy a metastasis was removed from the left temporal lobe of the

brain of this patient, but she died 1 year later with liver metastases

The literature is reviewed to ascertain if the spread of nonpapillary renal carcinoma was similar to the metastasis in this case. Very few authentic examples could be found.

ORMOND S. CULP, M.D.

A New Method of Implantation of the Ureter into the Urinary Bladder (Nový způsob implantace močového do měchy) LUDVÍK HAVLÁSEK, Lék. listy, 1948, 3: 545

At the Obstetrical and Gynecological Clinic in Brunn, Czechoslovakia, during the period from 1925 to 1947, 21 operations for fistula of the ureter were done. Twenty patients presented vesicovaginal fistulas, while 1 patient presented a combined vesicovaginal fistula with suprapubic extension through the operative scar. In 3 patients both ureters were involved. Seventeen of the cases resulted from the Wertheim panhysterectomy, 2 from the Schauta and 1 from a simple hysterectomy for cancer of the cervix, 2 from a simple hysterectomy for uterine fibromyoma, and 1 from injury during criminal abortion. Three of the patients were treated by nephrectomy and the remainder underwent vesicoureteral implantation.

From 1936 on, 6 of the patients were subjected to a modified Sampson implantation. In 1 woman the injury was bilateral, and it is these 7 implantations which form the basis of this report. The lower end of the proximal stump of the severed ureter is shaped into 2 flaps, as in the original technique of Sampson, and these are introduced through the incision in the bladder wall and then spread out and fastened to the inner surface of the bladder wall by mattress sutures passed back by separate nontraumatic needles through the bladder wall from the inside. The incision in the bladder wall is a simple cut made over the tips of a curved forceps introduced through the urethra into the bladder. The tips of the forceps then grasp another suture, which catches the ureteral wall above the flaps, and traction on this extra suture is what pulls the ureteral stump through the bladder incision into the vesical cavity. After the flaps are sutured, this extra suture, which is led out through the urethra, is then used for traction to pull the entire funnel shaped implantation area into the vesical lumen. The walls of this invaginated bladder wall are then stitched with finest catgut and the ureter above the area of implantation, and the latter area is left protruding in valvular fashion into the cavity of the bladder. The incision is placed as close as practicable to the original ureterovesical opening, and the distal stump of the ureter is closed and stitched in such a manner to the structures of the pelvis as to bring the mobilized bladder high up under the urethra (Latzko). The ureteral stump is implanted in an oblique direction through the muscular wall of the bladder and the folds are raised and stitched above the ureter as in the method of Witzel.

A retention catheter is left in place for 10 days or longer, the bladder is washed out daily with a weak

silver chloride solution and plenty of fluids, and urinary antiseptics are administered.

Two of the patients had received an injury during the Wertheim operation, the wound in each case was recent, clean, and especially favorable for cure. Both the immediate and late results were excellent. In the remaining 4 patients (in 1 of whom the injury was bilateral) a fistula had been present. Here again the immediate and later results were good, in the fourth woman the fistula recurred and cure was obtained by nephrectomy.

The patients of this group who were operated upon successfully were later subjected to cystoscopy, descending pyelography, and ureteral catheterization for periods ranging from 1 to 4 years. In every case the new aperture was wide, the urine was discharged rhythmically, yet in only 1 case could a reflux be detected. In 2 instances following the operation, a cystopyelitis lasted for a year or so, in the bilateral case the implantation was made into the vertex of the bladder and this was followed by much suffering (cystopyelonephritis) in the 4½ year period until the patient's death from carcinomatous metastases.

On the whole, however, the trifling disturbances, such as moderate dilatation of the ureter and kidney, pelvis, swelling and edema of the implantation flaps, and delay in the appearance of the dye in the kidney tests, tended to disappear in time. The author regards the operation, as here described, especially well adapted anatomically, biologically, and functionally, for the operative treatment of injuries and fistulas of the ureter.

JOHN W. BRENNAN, M.D.
SCHNITTMAN, J. *Urol*, Balt., 1948, 60: 421

Results in Ureterointestinal Anastomosis MORRIS

A slightly modified form of the Coffey I operation for ureterointestinal anastomosis is described. In a series of 12 cases in which this technique was employed the normal pyelograms were increased from 25 to 80 per cent as compared to results following the original Coffey I operation.

It is the author's belief that the close observation of the following principles was largely responsible for the improvement.

1. The rectosigmoid should be freely movable, if it is not, mobilization is indicated.
2. A minimum portion of the ureter should be freed, to prevent angulation and injury to the blood supply.
3. An adequate trough should be made. Lateral flaps at least 1.5 cm in width are formed. With the bowel held with moist saline gauze, a longitudinal incision is made in the taenia through most of the circular muscular fibers. However, a very thin layer of circular fibers is left intact with the mucous membrane "pouting out" in a few places. With the bowel grasped gently by the gauze covered hand and with the aid of a fixation forceps, the flap is started in the incised portion of the bowel where there are still a few intact circular fibers. The seromuscular layer is then peeled back in a plane between the severed and

intact circular fibers, at right angles to the line of the incision

The ureter is inserted into the bowel through a transverse incision in the mucosa

FREDERICK A LLOYD, M D

BLADDER, URETHRA, AND PENIS

Cystitis Emphysematosa MARIE ORTMAYER *J Urol*, Balt., 1948, 60 757

About 50 cases of human cystitis emphysematosa have been reported in the literature, four-fifths of these are autopsy reports. The condition is distinctive in that vesicles are formed in the mucosa of the urinary bladder. These are filled with gas. Investigation has shown that the infecting organisms can be made to grow with gas formation in vitro if the pH is favorable. The organisms cultured have nearly always been of the *Bacillus coli communis* group.

The disease is generally accompanied by bloody and frequent urination, rarely with pneumaturia, crepitation over the bladder area is sometimes felt. The plain x-ray film may show a ring of air outlining the bladder. The cystoscopic view is quite striking, with the shining, silvery vesicles standing out from the mucosal surface, these resemble air bubbles in their reflectability, and have purplish edges.

The author's patient was a 69 year old diabetic female who presented bloody urine with frequency. She was found to have a low grade fever, a high fasting blood sugar, and glycosuria. The bladder presented the appearance of being covered with air bubbles everywhere, many were hemorrhagic at their circumferences. The cysts were from 4 to 10 mm in diameter and, in places, were arranged in clusters. Some of these burst under vision, and released gas. The cultures of urine from the bladder and both kidneys yielded *Bacillus coli*. Cultures for tubercle bacilli were negative. A repeat cystoscopy 4 days later showed marked regression of the disease, only a few blebs remaining. The patient had a huge hydronephrosis and hydroureter which were removed surgically. She recovered completely.

This represents the twelfth case of this disease which has been reported after being discovered at cystoscopy.

JOSEPH E MAURER, M D

Condition of the Bladder and Ureters After Nephrectomy for Renal Tuberculosis (Sur l'état de la vessie et des uretères après la néphrectomie pour tuberculose rénale) PIERRE MURET *Bordeaux chir*, 1948, No 1 5

The author reports some representative cases following nephrectomy for renal tuberculosis on which he bases the following conclusions.

The nontuberculous ureteral stump undergoes very little change after nephrectomy, its tonicity and motility persist long after the operation without presenting any noticeable change. However, the lesions of the tuberculous ureteral stump, like those of the bladder, regress and disappear gradually, a process of fibrous cicatrization eliminates the speci-

fic lesions and fills the lumen of the ureter. Two years after operation permeability of the ureter is still the rule and obliteration the exception, but 3 years after operation the reverse is true.

The tuberculous ureter may be the source of complications, such as persistence of pyuria, urinary or purulent fistula, and ureteral abscess. These complications usually heal under simple therapeutic measures.

Ureteral reflux is induced by the changes in the bladder and bladder neck as much as by the ureteral lesions, it is a serious complication which menaces the function and favors tuberculous infection of the remaining kidney. Bladder denervation by pelvic neurotomy or anesthetic infiltration, or endoscopic resection must be tried in such cases, if these measures fail or if the bladder has lost all functional value through cicatricial contraction, ureterosigmoid anastomosis will give good results, but if the anatomic condition of the ureter does not allow this anastomosis, the last possible recourse will be cutaneous ureterostomy.

The author has noted a peculiar modality of certain residual urines when the bladder is filled with opaque solution, the kidney and ureter also become filled by reflux, if the catheter is then removed and the patient is made to void, the film taken immediately thereafter shows the bladder to be still filled (residue), but the kidney and ureter are empty. It would seem that in this case of passive reflux the residue does not designate difficulty in the evacuation of the bladder but a filling of the organ by the previous renoureteral contents. This would explain the usefulness of bladder drainage by an indwelling catheter.

As the ureteral stump may cause complications, it is more logical to prevent them by some simple precautions which do not aggravate the surgical intervention. Thus, exonephrectomy has given favorable results. In this procedure, section of the renal pedicle allows exteriorization of the kidney, which remains attached only by its ureter, the incision is closed completely, after which the ureter is cut between two clamps and the stump is kept exteriorized in the lower angle of the wound by a special clamp or a small collar of gauze. In cases in which the ureteral or periureteral changes make this procedure impossible, the sheathing method of Dor can be used. In this method, the ureteral stump, which has been cut by thermocautery between two clamps, is introduced into a tightly fitting drain by pulling on the stump ligatures that have been left long for the purpose. The wound is closed around the drain, which may be used to inject antiseptic substances.

RICHARD KEMEL, M D

Tumors of Diverticula of the Urinary Bladder (Les tumeurs des diverticules vésicaux) JACQUES MICHON *J urol méd*, Par, 1948, 54 438

Coexistence of diverticula and tumors of the bladder is not very rare, but the development of a neoplasm within a diverticulum is very unusual. Re-

ports of approximately 100 such cases, all in males, have been published. This is not surprising, inasmuch as diverticula as such occur nearly exclusively in the male sex, and the frequency of cancer of the bladder in men is three times as great as in women. Tumors in diverticula are found mostly in the sixth decade of life. In the majority of the cases reported, the involved diverticula were found on the posterolateral aspect of the bladder. Acquired formations are more frequently affected than congenital diverticula. The location of the tumors varies but most of them are at the base of the diverticulum. Malignant lesions are found seven times as often as benign.

Stagnation of the urine within the diverticulum and inflammation of its mucosa are predisposing factors.

Hematuria, slight or intensive, single or repeated, should arouse a suspicion of malignancy. In many instances, rectal examination may confirm the diagnosis. Cystoscopic and roentgenologic examinations are essential for the establishment of the diagnosis. Filling defects can be visualized better after a direct introduction of the opaque medium into the diverticulum than after cystography or intravenous urography.

Electrocoagulation may be employed for the treatment of benign papillomas but diverticulectomy is indicated in the presence of malignant tumors. The intraperitoneal route is the most popular either by the endovesical or extravescical method or a combination of both. As a rule, the endovesical method alone does not allow a radical extirpation of the diverticulum. The submucous endovesical method is recommended by some authors because it facilitates the preservation of ureters, but urograms and ureteral catheterization make the other methods equally safe. If the ureter is sectioned inadvertently, or if a part of it must be removed because it traverses the tumor, a reimplantation is not advisable. A nephrectomy, nephrostomy, or cutaneous ureterostomy is preferable.

Although not very efficient, x-ray therapy may be employed in advanced stages.

The prognosis of diverticular tumors is the same as that of other neoplasms of the bladder. In 1 case reported by the author a papilloma of the diverticulum was found concurrently with papilloma in another region of the bladder. In the 2 other cases a cancer of the diverticulum was present.

JOSEPH K. NARAT, M.D.
Extravesical Radium Therapy in Cancer of the Bladder R. OGIER WARD *Brit J Urol*, 1948, 20, 191

A new technique is described for radium treatment of malignant bladder growths. To date, the author has used it in 6 cases, 5 of which are reported. By this method, radium needles are brought into apposition with the neoplasm by implantation into the outer layers of the bladder wall without necessarily opening the bladder.

A complete preliminary study of the urinary tract, including cystoscopy and biopsy, is made routinely. The size, shape, and position of the growth are recorded to facilitate the extravescical placement of the radium needles at operation. The operating team includes a physicist to determine the dosage. At operation the bladder is mobilized and as the needles are placed in position from without, through a site determined to correspond to the intravesical site of the tumor, a continuous cystoscopic check is made to prevent penetration of the cavity by the needle. If penetration does occur, the needle must be withdrawn to an area within the bladder wall to prevent the formation of a fistula.

In this technique the bladder surface can be studied cystoscopically beforehand, the base of the tumor palpated, and the presence or absence of extravescical extensions can be seen at operation. Irradiation is given in maximum intensity to the base of the tumor, the part from which the most dangerous spread usually occurs. In the standard transvesical technique it is obvious that although the vesical surface of the tumor is in view, no estimate either of its thickness or of its extensions is possible.

No excessive claims are made for this method of treatment. In 2 instances dramatic palliative results were achieved which obviated the need for a mutilating operation. It is noted that in both of these cases there were no extravescical extensions.

GENITAL ORGANS

Cancer of the Prostate and Its Hormonal Management (Das Prostatakarzinom und seine hormonale Behandlung) EGON WILDBOLZ *Deut med Wschr*, 1948, 73, 305

The author is of the opinion that the understanding of the hormonal effect upon the cancers of the prostate gland has completely changed the general attitude toward this disease. He quotes a personal communication from Deming, to the effect that tissue transplants of carcinoma of the prostate will grow in the anterior chamber of the eye of male mice, but not in female mice unless they receive massive doses of testosterone. The chemical similarities between vitamin D and the estrogenic substance has led him to try this vitamin. He has observed a definite beneficial therapeutic effect.

Studies were carried out to observe the morphological changes in estrogen therapy. It was noted that there is a vacuolization of the cancer cells, shrinking of the nuclei, and a definite reduction in the mitotic figures.

In discussing the clinical aspects the author praises the value of the phosphatase determinations. These have helped both in the diagnosis and in the evaluation of the therapeutic effects.

The results of therapy are based upon a study of 77 cases. In 47 of these there was histologic proof of the diagnosis. Of the 77 patients, 60 were treated

with hormone therapy. The usual dosage was 5 mgm of stilbestrol per day. This was reduced to from 1 to 3 mgm as soon as the symptoms disappeared. Castration also was employed in a good many cases. The author believes that this is not sufficient as there is a return of androgen in the blood after a period of time. This may have its origin from vicarious manufacture of the hormone in some of the other glands of internal secretion, probably the adrenal. The author thinks that all of this therapy should be held in abeyance until symptoms other than those of urinary obstruction make their appearance. The obstruction can usually be managed by transurethral resection. One of the patients has survived 10 years with nothing other than several transurethral resections.

As the hormonal therapy is proving its worth it is creating a new approach to both the therapy and the knowledge of prostatic cancer. Yet it does not appear to be curative, so that selected cases should still be treated by radical perineal prostatectomy.

MISCELLANEOUS

Incontinence of Urine Caused by Dysplasia of the Vesical Neck, with Paradoxical Vesicoureteral Reflux. Nephroureterectomy and Young's Operation. Classification of Urinary Incontinence. (Incontinência urinária por displasia do colo da bexiga com refluxo paradoxal vesico-ureteral. Nefroureterectomia e operação de Young. Classificação da incontinência urinária.) GUERREIRO DE FÁRIA Hospital, Rio, 1948, 34: 795.

Complete incontinence of the urine caused by dysplasia of the neck of the bladder, a vesicoureteral reflux, and megaloureter were observed by the author in a man, aged 22 years, who was born with a meningoencephalocele, lumbosacral spina bifida, deformities of the spine and the pelvis, paralysis and atrophy of the right lower extremity, and incontinence of the urine and feces.

Intravenous and retrograde urography established the diagnosis of vesicoureteral reflux on the left side, congenital left hydroureter, and voluminous uronephrosis. The affected ureter and kidney were removed through a double incision, lumbar and pelvic. After the operation the pyuria disappeared and the incontinence became less pronounced. One and one-half years later the internal sphincter was repaired according to Young's technique. A follow-up study showed complete recovery of the bladder function.

The Treatment of Urinary and Genital Tuberculosis with Streptomycin. FREDERICK LLOYD, GEORGE BAUMRUCKER, and OLIVER STONINGTON. *Surg Clin N America* 1948, 28: 1639.

In an attempt to evaluate the effectiveness of streptomycin therapy in urinary and genital tuberculosis, the authors reviewed the cases of 23 patients who were treated with 1 gm. (in two divided doses of 0.5 gm. each) of this drug for a period of 120 days.

Sixteen patients completed the full course of streptomycin and were observed for periods of from 1 to 8 months following completion of the therapy.

The authors concluded from this series of patients that streptomycin is of very limited value when employed by itself in the treatment of urinary and genital tuberculosis in the male.

The symptomatic improvement that often accompanies its use is due to the temporary healing of the bladder lesions.

Renal tuberculosis with positive pyelographic findings does not respond well to streptomycin therapy; in fact, the destruction of the kidney may occasionally be accelerated by its use.

In the very early renal lesions with a low leucocyte count in the urine and with pyelographic findings, the response to streptomycin therapy may be excellent. A prolonged follow-up (5 to 10 years) will be necessary to determine if actual healing has taken place.

Streptomycin has little effect upon lesions in the male genitalia, but it does cause prompt healing of scrotal fistulas.

When used in conjunction with surgical treatment, the drug will undoubtedly prove to be of tremendous value, for the partial healing effect will probably be enhanced by the results of operative treatment.

The healing of tuberculous lesions in the bladder that respond slowly after nephrectomy are occasionally accelerated by streptomycin therapy.

When the bladder lesions do not improve because the ureteral stump fails to heal following nephrectomy, the use of streptomycin should render a second ureterectomy a far safer procedure.

Loin fistulas and postoperative tuberculous wound disruption heal promptly when using streptomycin therapy.

CONRAD A. KULHN, M.D.

Report of the Clinical Cancer Research Committee of the British Empire Cancer Campaign. *Brit Empire Cancer Campaign*, 1947.

The Clinical Cancer Research Committee has submitted an exhaustive clinical compendium of 50 pages comprising a detailed statistical analysis of 156 cases of cancer of the kidney, 451 cases of cancer of the bladder, and 399 cases of cancer of the prostate.

Tumors of the kidney comprised 144 primary lesions and 12 recurrent lesions. Except for the teratomas, which were equally distributed among males and females, the majority of these tumors occurred in males (2 or 3 males to 1 female). The mean ages were from 57.0 to 58.6 with no statistically significant differences between the groups, except in the case of teratomas in which group the mean age was 32 years. No relevant causative factors were found on investigation of the patient's occupation, heredity, or past history. Hematuria was the commonest initial symptom, except in patients with teratomas, in whom the discovery of a tumor often preceded the onset of any symptoms.

In 10.5 per cent of patients with carcinoma, the primary lesion was silent and the first symptoms no

ticed were those due to metastases. While three-fourths of the patients had consulted a doctor within the first 3 months, and as many were immediately referred to the hospital, one-fourth were found to have recognizable metastases on admission. Nephrectomy was performed in 42.1 per cent of the patients with carcinoma, in 75.0 per cent of patients with teratomas, and in 71.0 per cent of those with growths in the pelvis of the kidney. Seventy-six patients were operated on with a mortality of 13.2 per cent. In cases in which the treatment consisted of complete nephrectomy with removal of fat and fascia and with or without x-ray therapy, the 5 year survival was 34.5 per cent. In cases in which the kidney alone was removed with or without adjunctive radiation therapy, the 5 year survival was 26.9 per cent. There were no 5 year survivals among those cases in which radiation therapy alone was employed. No statistical difference was found to exist among the cases of hypernephroma and carcinoma. The number of cases in which metastases developed before discovery of the primary tumor, and operability and survival rates were similar.

Tumors of the bladder comprised 423 primary lesions and 28 recurrent lesions. The ratio of males to females was 3 to 1. The mean age of the males was 63.5 years, and of the females 65.9. A statistical difference was found to exist in the occupational levels, a higher preponderance was observed in the skilled worker class. The past histories were irrelevant, however, 16.1 per cent of the patients had had treatment for previous attacks of hematuria which had been diagnosed as papilloma of the bladder. Painless hematuria was the first symptom observed in 69 per cent of patients, and other urinary symptoms were observed in 26 per cent. The initial symptoms were those caused by metastases in 1 to 2 per cent of cases, and discovery by cystoscopic examination of a symptomless primary tumor occurred only 3 times (0.7 per cent). In spite of the incidence of hematuria, only 54.4 per cent of the patients consulted a doctor within the first 3 months, 15 per cent of patients had had symptoms for 6 months or more before consulting a physician. Cystoscopy was performed in 82.3 per cent of all patients, in 82.5 per cent of cases the tumor was considered to be malignant, in 82.0 per cent of the patients normal kidney function was present, 170 of the tumors were of the papillary type, 2 were myxosarcomas, and the remainder were infiltrating carcinomas, 79 lesions ex-

tended beyond the bladder, there were 14 cases of distant metastases. One hundred and eleven patients with papillary carcinoma underwent radical therapy, with an operative mortality of 13.5 per cent and a 5 year survival rate of 29.7 per cent. Of the infiltrating carcinomas, radical procedures were possible in 69 cases, with an operative mortality of 18.8 per cent and a survival rate of 14.5 per cent. Radiotherapy alone, which was used in 24 cases of papillary carcinoma and 36 cases of infiltrating carcinoma, gave survival rates of 8.3 per cent and 2.8 per cent, respectively.

Prostatic tumors comprised 399 cases in the survey, of which 383 were primary, and 16 were recurrent. The mean age was 67.4 years and the maximum incidence was in the age period from 65 to 70. There was no statistical difference in the occupational study, or in the past history of patients. The first symptom of the disease was difficulty or frequency of micturition in 60 per cent of patients, however, in 21 per cent of patients the first symptom noticed was referred pain or other symptoms pointing to the possible presence of a metastasis. In 53.5 per cent of the cases the patient consulted a doctor within the first 3 months, but in about 20 per cent of cases the disease had existed for more than 6 months when the patient was first seen, 58.3 per cent of the patients were referred to the hospital at once, but 17.3 per cent were kept under symptomatic treatment for more than 3 months. On admission, 27 per cent of the patients had clinically recognizable metastases of which 8.1 per cent were bony metastases. So called radical operations were performed on 38 patients, in 24 of whom the diagnosis of malignancy was made by means of the microscope, after an enucleation operation for a supposedly benign condition had been performed. The operative mortality for the so called radical operations was 7.9 per cent. Transurethral resection was performed on 44 patients, with an operative mortality of 15.9 per cent. In the advanced cases, suprapubic cystostomy alone carried an operative mortality of 22.6 per cent, but the expectation of life was raised thereby, from 31 per cent (which was the level among the untreated patients) to 49.3 per cent, according to the stage of the disease. Radiotherapy achieved about the same results. Estrogenic therapy had not been introduced at the time these cases were registered.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Giant Cell Tumor of the Sacrum A Case Report RALPH F. BOYERS *Ann Surg*, 1948, 128: 1164

The author presents the case report of a giant cell tumor of the sacrum in a 29 year old white male who had fallen from a truck about 7 months before admission to the hospital. One week after falling he noticed pain in the lower back in the sacral region, and 3 weeks later he noticed slight swelling in that region. Pain was accentuated by prolonged sitting. For 3 or 4 months prior to admission to the hospital he noticed numbness in the posterior aspect of the left leg. There was approximately 40 pounds of weight loss with illness.

Physical examination revealed a well developed, undernourished, white male with findings limited to the lower back and rectum. There was a large, ovoid, pulsating swelling located centrally in the region of the sacrum. Over the mass were many dilated blood vessels and there was slight tenderness to palpation. Rectal examination revealed a protrusion of the sacral mass against the rectal wall, displacing the rectum anteriorly. Pulsation could be felt by the examining finger.

Röntgenograms showed the entire sacrum, with the exception of the proximal end, to be destroyed, replaced, and expanded in all diameters with a thin shell of subperiosteal new bone remaining irregularly distributed over the surface of the tumor and a few strands of bone remaining with it. The coccyx was partially destroyed.

Several roentgenologists were consulted but each was hesitant, due to the pulsating nature of the neoplasm and fear that too much radiation would be necessary. Surgery was therefore decided upon although it meant the sacrifice of sacral segments II, III, IV, V, and the coccyx, and all the sacral nerves below the first.

The first operation was done with the patient in the prone position. The vascularity was so great that after 5 hours of operating time the procedure was abandoned and the skin closed. The patient recovered rapidly and in approximately 3 weeks a left rectus incision was made near the midline. After the common iliac vessels were exposed and occluded, cessation of the pulsations in the tumor was observed. Occlusion of the hypogastric vessels also completely stopped the pulsation. These vessels were doubly ligated and transected, and both common iliac arteries were occluded with umbilical tapes. The laparotomy wound was closed with through-and-through silver wire sutures and the patient was placed in the prone position. The old posterior wound was reopened and the cleavage plane at the coccygeal end was re-established. The tumor was then freed and removed with little bleeding. The

skin was closed loosely with drainage of the huge dead space. The first sacral nerves were intact but the remainder were necessarily sacrificed. The patient was again placed in position for laparotomy, the wire removed, exposure regained, and the tapes removed from both common iliac vessels. The abdominal wall was closed and the patient was returned to the ward in good condition.

Microscopic section showed this to be an extremely vascular but typical benign giant cell tumor with areas of bony tissue scattered throughout its substance.

The laparotomy wound healed per primam, but the sacral wound was finally healed by Thiersch grafting.

Upon discharge from the hospital, about 1 year after operation, rectal and urinary sphincters were not functioning, there was anesthesia over a small area perianally, and hypesthesia extending down the posterior aspects of both legs and in the heels. About 2 years and 3 months after removal of the tumor a questionnaire elicited the information that the patient performed light work around a small shop and his house, and claims that his legs "play out" after vigorous exercise. There is no control of urinary or rectal sphincters. A Cunningham clamp is worn and a constipating diet is followed. His weight is normal and his appetite good. Permanent cure of this benign tumor may now be expected.

RUDOLPH S. REICH, M.D.

Developmental Coxa Vara A. B. LE MESURIER, J. *Bone Surg*, 1948, 30-B: 595

The present article is based on 15 cases of developmental coxa vara admitted to the Children's Hospital, Toronto, and 1 other case which was first seen at the age of 43 years.

Despite a fairly extensive literature, and probably because the condition is not common, its real nature and severity have seldom been recognized as soon as they should be, and treatment has not usually been started until there was marked deformity. The condition is characterized by the development, at the age of about 3 or 4 years, of a limp or waddle which is usually painless, and is progressive. A varying degree of coxa vara deformity is present on one or both sides, but the most striking feature is the roentgenographic appearance of a gap in the neck of the femur just distal to the epiphyseal line, together with a bend in the femoral neck at this level. This x-ray appearance is, in itself, almost sufficient to establish the diagnosis of coxa vara deformity as soon as the patient is first seen.

In the treatment of late cases, unless the deformity is very severe, limitation of abduction can be overcome and shortening can be reduced by osteotomy between the trochanters, or below them, the lower fragment being abducted widely.

This operation was performed on 12 hips. The osteotomy united rapidly and the limp either disappeared or was much improved. Besides overcoming deformity, the gap in the bone healed completely within a year and in a much shorter time than would have been possible without operation, with a single exception. In the one case in which the gap failed to heal, the fragments probably were not abducted widely enough. At the end of 2 years the gap was still open and the deformity of the neck had increased. Recently another osteotomy was performed on this patient with more abduction of the fragments.

In the early cases, the most important thing is to close the gap before deformity becomes disabling and it would seem better, if possible, to do this without osteotomy, which may distort the mechanics of the hip. Since healing of the gap after osteotomy seemed to be due to elimination of the shearing forces, it was thought that the same result might be obtained by insertion of a Smith-Petersen nail. This was done in one hip of a patient. After a period of 11 months, the gap was still widely open. In the other hip of the same patient, a few days after nailing the first hip, a large drill was passed up the neck of the femur into the head, into this drill hole two tibial bone grafts, placed cortex to cortex, were inserted tightly. Eleven months after operation, the gap in the bone was pretty well healed, repair was much more advanced than on the side which had been treated with a Smith-Petersen nail.

Since then 2 other cases have been treated by grafting, in both the gap is healing well, one after 3 months and the other after 4 months. It would seem that this is much the best way to secure closure of the gap. The most striking thing about these 3 grafted cases (one with a nail in the other hip) is that all are walking and running normally and all have lost the limp they had before operation, although there has been no change in the degree of coxa vara deformity. It would appear that weakness or instability at the site of the gap in the bone is an important element of the limp, and that if the gap can be closed before the coxa vara becomes sufficiently severe to cause disability, the symptom should disappear.

RUDOLPH S. REICH, M.D.

Patella Cubiti. A New Method of Treatment for Its Avulsion. JOSEPH SACHS and GEORGE DEGENSHEIN
Arch. Surg., 1948, 57: 675

Patella cubiti is a condition of the elbow wherein a patella-like bone lies proximal to the olecranon process within the investments of the triceps tendon. A review of the literature reveals that less than 25 cases have been reported to date. The cause of the condition is a subject of much debate. There are two schools of thought—one, that the condition is a congenital anomaly, the other, that it is of traumatic origin.

The patient with patella cubiti is always asymptomatic except for mild limitation of extension which may go unnoticed. Discovery of this anomaly is

usually coincidental when other conditions require that roentgenograms be taken. Avulsion of a patella cubiti presents a definite clinical picture. The patient usually gives a history of extension force on the elbow, followed by pain and inability to extend it, on palpation, a moderate sized bony fragment may be felt posterior to the lower end of the humerus. The fragment is usually mobile and cannot be brought down to the elbow joint unless the elbow is extended.

Roentgenograms reveal a sesamoid bone which, when avulsed, lies perhaps 1 to 2 cm proximal to the olecranon, when not avulsed it lies immediately proximal to the olecranon and articulates with it. All edges of this bone are smooth. The most important (roentgenologic) diagnostic feature is the fact that the combined measurement of the ulna and the sesamoid is greater than that of the opposite normal ulna, or, in the case of a bilateral patella cubiti, longer than would be expected from the length of the related radius. This diagnostic feature will help differentiate patella cubiti from traumatic fractures or from avulsion of the olecranon process, with which it is sometimes confused.

In the report of a case submitted by the authors, a 21 year old white male was admitted to the hospital with a complaint of pain in the left elbow. On examination, the patient could flex but not extend the elbow. A clinical diagnosis of fracture with avulsion of the olecranon was made. A roentgenogram revealed the presence of a patella cubiti in the left elbow, measuring $3\frac{1}{2}$ by 1 cm, and separated from the olecranon by at least 2 cm. Roentgenograms of the right elbow revealed a patella cubiti separated only 1 to 2 mm from the olecranon.

Open operation was performed. The distal end of the triceps tendon, after it enveloped the sesamoid, was torn from its olecranon attachment and markedly thinned out so as to prevent adequate suture. The articulating surfaces of the sesamoid and the olecranon were smooth, glistening, geographic, and were covered with a serous membrane, and they contained a sparse amount of hyaline cartilage.

A No. 32 self-tapping Sherman vanadium steel screw was introduced which firmly fixed the sesamoid to the head of the olecranon. The elbow was immobilized in plaster at a 90 degree flexion for 4 weeks. The wound healed per primam. The patient improved progressively and on follow-up visits to the clinic there was evidence of rapid return of extensor function, but a mild weakness of the extremity was observed.

The patient was then inducted into the Navy and he was hospitalized for complaint of weakness in the left arm. With rest and physical therapy, he gained progressively until approximately 1 year after operation when he was able to perform all functions with the elbow.

After a period of 3 years the arm with the avulsed patella cubiti has as much extension as, or even a little more than, the one on the opposite side, and there is no residual weakness.

RUDOLPH S. REICH, M.D.

Knee Pain of Muscular Origin (Muskulaer bedingte Knie-schmerzen) HERMANN RICHTER *Chirurg*, 1948, 19 451

It is well known that pain in the knee joint may be a result of abnormality elsewhere than in the knee joint itself. Familiar examples are the pain caused by hip joint disease, flat foot, bowlegs, absence of the metatarsal arch of the foot, and by other deformities of the leg and foot. In addition, there are numerous patients who complain of knee pain without demonstrable abnormality in the joint itself and without evidence of any of the conditions mentioned. In most of these cases there is some muscular insufficiency of the lower extremity resulting from muscular degeneration. The gastrocnemius muscle, particularly its medial belly in the middle and upper portions, is most frequently and most severely involved. Often there is muscular degeneration in the adductors, in the hip musculature, or in other muscles of the leg. These patients do not complain of muscular pain, but the indurated muscle segment may be palpable and may be sensitive to pressure, although deep lying muscular degeneration may not be palpable. Muscular degeneration may be a result of overstretching or of a rheumatic type of abnormality or both. In another group of patients with knee pain, localized tenderness may be found over the origin of the gastrocnemius muscle from the femur. The medial head is most frequently affected. This syndrome resembles epicondylitis.

Benefit may be obtained from treatment with adhesive strapping or other means of support and immobilization. Compression bandages applied to the affected muscles may help. Various modalities of physical therapy are beneficial. In severe cases bed rest or immobilization in a plaster cast may be necessary. If the condition appears to be related to occupational strain, it may be advisable to change the occupation. JOHN L. LINDBLUM, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Arthroplasty in Cases of Congenital Dislocation and Subluxation of the Hip in Children (De l'arthroplastie dans les luxations et sub-luxations congenitales de la hanche chez le jeune enfant) HENRI LAFFITTE and PIERRE SUIRE *J. Internat. chir.*, Bruxelles, 1948, 8 968

This report is based on 23 operations on 16 children with 10 subluxations and 13 dislocations. All of these children had control of urination and defecation. The youngest child was 5 years old. Preceding the operation, motion of the affected hip was encouraged.

Ollier's incision was used and carried down to the joint. The femoral head was reshaped and the acetabulum was made deeper to fit the femoral head. The capsule was sutured tightly. The bone graft was usually taken from the base of the trochanter, measuring 4 by 2½ cm, and it was between 4 and 5 mm thick. The graft was removed downward

from the top and was fixed to the supra acetabular region with catgut. Penicillin was given routinely and immobilization was secured with plaster. The hip and knees were flexed about 20 degrees with the leg in 30 degree abduction.

GEORGE I. REISS, M.D.

FRACTURES AND DISLOCATIONS

A Study of Results Obtained in the Treatment of Fractures of the Lower End of the Radius in Insured Persons in Finland OLLI VALTONEN *Ann. chir. gyn. fenn.*, 1948, 37 287

It is estimated that from 2,500 to 3,000 fractures of the lower end of the radius occur annually, in Finland. The author's study is based upon 425 cases which occurred in 1936, all of them in insured persons. Two-thirds of the patients were treated by general practitioners, and one-third were treated in outpatient departments or by specialists in surgery. The average duration of treatment was 46.2 days. The results of treatment were good in 72.5 per cent, fair in 10.6 per cent, unsatisfactory in 10.1 per cent, and poor in 6.8 per cent of the cases. Permanent disability did not exceed 10 per cent in any case. The normal anatomy was restored in 86.4 per cent of cases. Better results were obtained by specialists in surgery than by surgeons in outpatient departments or general practitioners. Good results were obtained by specialists in 81 per cent of cases and by outpatient department surgeons in 74.2 per cent, while general practitioners obtained good results in 69.7 per cent.

Good results were impaired by advanced age, failure of reduction, and prolonged immobilization. Three cases were complicated by rupture of the extensor pollicis longus.

DANIEL H. LEVINTHAL, M.D.

Fractures of the Neck of the Femur T. G. HUGHES *Hogg Med. J. Australia*, 1948, 2 593

The present article on fractures of the femoral neck has been divided historically into phases.

The negative phase was classified as that in which nothing constructive was done to reduce the fracture or maintain the reduction, with the result that non-union of fractures was the rule, and the mortality was high.

The abduction phase dates from about 1800, when Whitman reduced the fracture of the femoral neck, placed the limb in wide abduction and internal rotation, and then fixed the lower extremities in a plaster cast. From 40 to 50 per cent of the fractures united, although a stiffness developed in the knee joint. The blood supply to the head of the femur was impaired and it was difficult, with the plaster spica, to prevent rotation movements of the fractured area. The American Orthopaedic Association appointed a committee to study this method. The end results in 201 cases showed a primary mortality of 28 per cent and bony union in 30 per cent of the patients 12 months after injury.

The operative (nailing) phase had its new start in 1931 by Smith-Petersen. The results reported were as follows: mortality in 10 per cent of cases, bony union in 75 per cent, and nonunion in 15 per cent. In the second part of the third, or operative, phase subtrochanteric osteotomy was used (1941). The final results in 75 cases reported by the Royal British Infirmary showed bony union in 58.7 per cent, bony union and arthritis in 1.3 per cent, nonunion in 8 per cent, fibrous union in 13.3 per cent, and doubtful results in 10.7 per cent. Results in 50 consecutive fracture cases reported by King showed bony union in 37, nonunion in 3, death in 7, results unknown in 3.

At Launceston General Hospital 27 selected patients were operated upon for fracture of the neck of the femur. Three patients died, 7 were not traced, and 17 were examined 2 years after operation. Among the remaining 14 cases, there were 2 cases of nonunion, 6 cases of bony union with good results, and 6 cases of bony union with osteoarthritis.

RICHARD J. BENNETT, JR., M.D.

Partial Patellectomy in Fractures of the Knee

(Patelectomia parcial en las fracturas de la rótula)

ARNOLDO E. DIDIER *Bol. Soc. cir. Rosario*, 1948, 15: 196

Preservation of knee function is the single standard required of any therapeutic measure for the treatment of patella fracture. The choice of suture material and other elements of repair are secondary. Prolonged immobilization of the knee joint often results in ankylosis or at least the development of adhesions requiring considerable physical therapy for their correction.

Total patellectomy obviates these difficulties, but the author believes partial patellectomy has further advantages and produces superior results. Partial patellectomy according to the Thompson technique permits re-establishment of the continuity of the tendon and ligament without the inconvenience of total patellectomy.

Twenty cases are reported. In the last 4 the Prince and Stein modification was employed. This consists in attaching the separated muscle and tendon ends to the under surface of the patella by a suture through the body of the patella.

STEPHEN A. ZIEMAN, M.D.

Refractures in Children (Ueber Refrakturen im Kindesalter)

ADALBERT BUETTNER *Chirurg*, 1948, 19: 347

The author observed 37 cases of refracture through the original fracture line over a period of 20 years. These were usually refractures of the forearm bones. He found that the bones were most vulnerable between the third and fifth weeks.

Fracture through the epiphyses healed the fastest. Refractures healed somewhat slower, but those occurring in the metaphyseal region healed faster.

The degree of angulation of the fracture fragments was directly proportional to the delay in callus formation. Angulation in the lateral direction delayed

union especially. Usually lack of bridging callus on one side preceded the refracture. In adults, pain at the fracture site was an important sign. In children, however, pain was usually absent. The refractures were usually more severe than the original fractures. If a fracture occurred after firm union of the original fracture had been established it usually occurred at a different location. This type of fracture should be classified as a new fracture.

GEORGE I. REISS, M.D.

ORTHOPEDICS IN GENERAL

End Results of Excision of the Carpal Bones

JAMES K. STACK *Arch. Surg.*, 1948, 57: 245

Inflammation of the wrist results in (1) capsular and ligamentous fibrosis, which is not confined to a single articulation because of the intercommunication of the various component joints of the wrist, (2) a cystic change in the carpal bones, especially those which bear the greatest functional burden, due to the hyperemia induced by the primary lesion, and (3) an arthritic change due to either a necrotic change in the articular cartilage or friction from the necrotic bones acting as a foreign body in the joint mechanism.

These changes may result also following removal of all or a part of one of the two portions of the scapholunate system which forms the intermediary joint between the capitate bone and the distal radius. In the readjustment which takes place following the excision the capitate tends to approximate the radial articular surface and displaces the remaining member of the scapholunate system, and the ligamentous strain causes inflammation. There will be, in addition, the scraping effect of cartilages working out of alignment.

Removal of a single bone or a large portion of one of them is not a good procedure, however removal of the lunate bone together with the navicular will result in no significant deviation, functional or cosmetic. Such a removal is really a very favorable type of arthroplasty, all of the remaining surfaces being covered with articular cartilage. If fibrosis has already become established the operation will probably not overcome it, but pain will be relieved and a stable, useful range of motion may be expected.

The author presents 9 wrists which have been treated by excision of the scaphoid and lunate bones, and these are the basis for this article.

NEWTON C. MEAD, M.D.

Congenital Discoid Meniscus

I. S. SMILLIE *J. Bone Surg.*, 1948, 30-B: 671

Twenty-nine congenital discoid menisci were encountered by the author among 1,300 meniscectomies performed between 1941 and 1948.

These menisci are classified as follows: (1) primitive—the very large, complete discs, (2) infantile—approaching the normal meniscus, and (3) intermediate—the type of abnormality found between (1) and (2).

The relative thickness of the periphery and central margins of discoid menisci does not, on the whole, differ greatly from that of cartilages unrelated to the classification

Injuries or sequelae sustained by the primitive discoid cartilage may be summarized as (1) a plane of cleavage or splitting ensues in the structure of the fibrocartilage between the undamaged superior and inferior aspects (2 in the 29 cases), (2) longitudinal tears are superimposed, usually on the inferior surface (4 cases), (3) the inferior surface is worn away and a shallow crater is produced, (4) both inferior and superior aspects are worn away, thus producing a defect (hole) in the center of the disc (2 cases)

The author, as well as other writers, has alluded to the "snapping knee." No one has precisely commented on the mode of origin. It is the author's opinion that one or more ridges develop on the superior aspect of discoid fibrocartilage and that somewhere between slight and full flexion of the femoral condyle, the acoustic phenomenon is elicited by virtue of a sudden forward excursion of the disc. Other causes of snapping are osteochondritis dissecans, impingement of the same on the tibial spine, and unstable knee joint

The intermediate disc differs categorically from the primitive in that it is less massive, less complete, and is thin at the central zone to the point of transparency. In addition to these principal differences, the intermediate disc is characterized by two notches in the central (thin) zone. Injuries of the intermediate disc are peripheral or extraperipheral longitudinal tears, which do not differ from those found in the lateral menisci, of noncongenital variety

The infantile disc varies from the normal lateral meniscus in increased breadth of its middle segment. It is comparable to one found in a full-term fetus. Six such cases were encountered in the series. Injuries sustained in this group of congenital menisci were those of incomplete transverse or oblique tear involving the lateral cartilage

Nine cases of cystic degeneration of the menisci were encountered in the series. Five were associated with primitive discs and 4 with infantile specimens. Trauma is said to be a factor

Although primitive medial menisci are said to be rare, the author describes one case reported in the literature and adds one of his own. These are the only cases of medial menisci described to date

SAMUEL L. GOVERNALE, M D

Knee Joint Changes After Meniscectomy T J FAIRBANK *J Bone Surg*, 1948, 30-B 664.

Radiological studies among 80 medial meniscectomies showed ridge formation involving the femoral condyle in 43 per cent of patients, narrowing of the interarticular space in 32 per cent, flattening of the femoral condyle in 18 per cent, and no change in 33 per cent of the cases. Lateral meniscectomy was performed in 27 cases. Little or no change was observed in 50 per cent, ridge formation of the homolateral femoral condyle was found in 7 per cent, while

narrowing was found in 40 per cent, and flattening in 17 per cent of the cases

The present investigation demonstrates that sustained weight-bearing in a meniscectomized patient results in circumferential compression and/or spread of a condyle devoid of a meniscus. The adverse cartilaginous change may ensue from increased friction, and from nutritional and mechanical factors due to interarticular overload

In conclusion, the author maintains that the formation of a ridge, narrowing of the joint space, and flattening of the femoral condyle are attributable to loss of weight-bearing function of the meniscus. Furthermore, meniscectomy is not wholly innocuous and may predispose to early degenerative changes in the joints

SAMUEL L. GOVERNALE, M D

The Etiology of Peroneal Spastic Flat Foot R I HARRIS and T BEATH *J Bone Surg*, 1948, 30-B 624.

There has been wide acceptance of the thesis that spastic flat foot is caused by peroneal muscle spasm induced by painful stimuli arising from the tarsal joints. This is brought about by the abnormal stresses thrown upon these joints during the flexible phase of these weak, flat feet

This theory does not explain why in many cases electromyographic studies indicate that no spasm of the peroneal muscles exists. Instead, these muscles have become shortened by adaptation to long-continued deformity, and the condition is not corrected by novocain block of the peroneal nerve, section of the nerve, or by anesthesia and cure in many cases. The author thinks that the spastic flat foot is probably congenital in origin and rigid from the onset. He believes that most so called "peroneal spastic flat feet" are due to tarsal anomalies, usually a talocalcaneal bridge of bone or a calcaneonavicular bar

A series of 17 cases of peroneal spastic flat foot, which have been studied in the last 2 years, have presented a talocalcaneal bridge in 12 instances, a calcaneonavicular bar in 3 instances, and rheumatoid arthritis in 2 instances

The talocalcaneal bridge can be well demonstrated with roentgenograms but only by means of a special positioning technique (Figs 1 and 2) which will show the joint between the sustentaculum tali and the neck of the talus in a normal foot but not in a foot with a talocalcaneal bridge. Lateral x-ray projections will show marginal lipping of the talonavicular joint on its dorsal surface due to abnormal motion and strain at this point secondary to the limitation of movement in the subtalar joint

Anatomists have attributed the talocalcaneal bridge to the fusion of the "os sustentaculi" to both the calcaneus and the talus, and it may be of either bone or "gristle." How this forces the calcaneus into the valgus position is obscure. This condition is probably often diagnosed as a congenital equinovagum deformity. There may be surprisingly few symptoms despite severe deformity. The calcaneonavicular bar may be present and associated

Fig 1 (Harris, Beath) Radiographic projection necessary to reveal talocalcaneal bridge. The central x-ray beam is projected downward and forward at an angle of 45 degrees, through the heels which have been freed of the leg shadow by flexing the knees

with neither deformity nor symptoms. When symptoms are present they usually consist of severe deformity, pain, and weakness. At other times symptoms follow a wrenching injury of the foot which avulses the calcaneus from the navicular. These symptoms subside with rest but reappear if early exercise is permitted.

Rheumatoid arthritis with peroneal spastic flat foot is entirely different from peroneal spastic flat foot with tarsal anomalies. To describe its true nature, it should be referred to as "arthritic flat foot with peroneal spasm." The orthopedic treatment of these cases may require manipulation under anesthesia to correct the deformity, and plaster casts to

Fig 2 Roentgenogram obtained by the technique depicted in Figure 1, in a patient who had a talocalcaneal bridge on the left side (A). On the right side (B), which is normal, the joint between the sustentaculum tali and the neck of the talus can be seen.

maintain the correction. The Whitman type of foot supports is useful.

Treatment of the rigid flat foot with tarsal anomalies is usually surgical, i.e., fusion of the subtalar and talonavicular joints is usually required. The author performs this operation through a medial incision in order to expose and remove the synostosis, which he believes is essential. In severe cases a lateral incision also is required to lengthen tight tendons.

In children too young for fusion of the tarsal joints, it may be necessary to resort to manipulations under anesthesia followed by corrective plaster casts. Whitman plates may give the necessary support in less severe deformities. NEWTON C. MEAD, M.D.

In selected cases arteriotomy and removal of the thrombus, followed by heparinization, may permanently re-establish the circulation

In venous thrombosis the author limits the use of heparin to patients whose general condition contraindicates the operation and to those in whom thrombosis is confined to the lower leg, because ligation of the popliteal vein may augment the obstruction. Ligation of a major vein just above the thrombus should be supplemented by the administration of heparin. In selected cases ligation above and below the thrombus, in order to prevent its spread in either direction, may prove beneficial.

The author performed thrombectomy in 4 cases of acute venous thrombosis, in 2 the results were excellent while in the other 2 the thrombosis recurred after cessation of the heparin treatment. The corresponding artery is temporarily clamped, the vein is incised, a circular compression is applied from the foot in the proximal direction, and the arterial clamp is released.

The author advocates more extensive use of arteriography or venography, respectively, in vascular occlusions.

JOSEPH K. NARAT, M D

Unexplained Thrombosis of the Internal Carotid Artery

H. R. I. WOLFE *Lancet*, Lond., 1948, 2: 567

The case is reported of a 26 year old white female, apparently in good health, who suffered an acute onset of severe temporal headache, muscular collapse without loss of consciousness, and aphasia and weakness of the right arm. Three days later weakness of the right leg occurred, after which she enjoyed a gradual but incomplete recovery. Nine days after the onset, arteriography revealed thrombosis of the internal carotid artery and periarterial stripping was carried out at the same time. Because of gradual deterioration of the condition a superior cervical ganglionectomy was performed on the left side 11 months after the onset, and the left external and internal carotid arteries were divided between ligatures. A firm white thrombus, incompletely canalized, occluded the internal carotid artery. Eighteen months after the onset there were slight mental deterioration and aphasia, and remnants of hemiplegia were observed on the right side.

Syphilis, tumor, arteriosclerosis, thromboangitis, berry aneurysm of the circle of Willis, early Christian Schueller's disease, minute injury to the vessel because of muscular exertion or abnormally developed fascial bands, and cardiovascular disease are mentioned as possible causes of the lesion on the basis of 32 cases reported elsewhere. The transient

nature of the early signs and symptoms, and the usual progressive later course are suggestive of cerebral vascular disease, but arteriography is necessary for the precise diagnosis.

Neither heparin nor dicumarol seems to have been used in the cases reported in the literature and the author suggests that if the diagnosis in his case had been determined earlier, alteration of the clotting time might have prevented further extension of the thrombus. In about half of the 33 cases reported in the literature and diagnosed by arteriography, there has been a gradual amelioration of the symptoms. There were 7 deaths, 2 being due to intercurrent infection.

ALLAN D. CALLOW, M D

Histopathologic Contribution to Our Knowledge of Buerger's Disease (Obliterating Thromboangitis)

(Contributo istopatologico alla conoscenza del morbo di Buerger (Tromboangioite obliterante))

ALFONSO TROJANIELLO *Ann. Ital. chir.*, 1948, 25: 555

Histologic studies made by the author on two lower extremities which had been amputated because of gangrene due to Buerger's disease led to the following conclusions:

Inflammation, presumably of an infectious character, is an important factor in the pathogenesis of Buerger's disease. Usually a constitutional organic condition is present.

As a rule, the initial changes in the intima of the affected blood vessels are of a degenerative and proliferating character. Gradually a parietal thrombus develops. The second phase of the condition is characterized by cellular infiltration, with endothelial, polynuclear, histiocytic, and lymphocytic formations participating in the process. The changes lead to the organization of a thrombus. A new formation of blood vessels contributes to canalization of the thrombus, which may result in a partial re-establishment of the circulation through the obstructed blood vessel.

The veins accompanying the arterial trunk, and the fibrous sheaths participate in the process. A new formation of blood vessels tends to create a collateral circulation and may thus be regarded as a functional compensatory factor.

The proliferative process involves also the perineurium, endoneurium, and the vasa nervorum.

The author's findings emphasize the importance of the vascular spasm in the thrombotic process. Such spasm accentuates the ischemia of tissues which eventually may cause gangrene.

SURGICAL TECHNIQUE

ANTISEPTIC SURGERY, TREATMENT OF WOUNDS AND INFECTIONS

Rapid Disinfection of Clean Unwashed Skin A D GARDNER and E VINCENT *Lancet*, Lond., 1948, 2 760

There is little object in using slow methods of disinfecting skin in preparation for surgery when more rapid methods are as good or better. In some emergencies, moreover, rapid skin disinfection is indispensable. Thus, experiments were carried out to test the effectiveness of various agents on areas of the shaven, but not specially washed, skin of the forearm which were infected with the *Pseudomonas pyocyanea*, in most cases. Agar plates were employed to culture such areas of infection as well as control areas.

These studies revealed that 1 per cent iodine in 70 per cent ethyl alcohol was effective in the least time taken for the disinfectant to dry on the skin, 15 to 20 seconds. If the solution was allowed to act in the wet state for 30 seconds, 0.5 per cent iodine was found to be sufficient. No iodine was necessary when the interval was extended to 2 minutes, 70 per cent alcohol alone serving adequately. The detergents, zephiran 30 per cent, and cetrimide 10 per cent, both in 70 per cent ethyl alcohol, were found, in 30 to 45 seconds, nearly to equal the performance of alcoholic iodine as rapid disinfectants.

Pure ether and mixtures of ether and alcohol proved to be less satisfactory. In vitro bactericidal tests, pure ether does not kill even small doses of cocci in 30 seconds nor large ones in 4 minutes, although it does kill large doses of the *Pseudomonas pyocyanea* and *Bacterium coli* in 1 minute and small doses in $\frac{1}{2}$ minute.

Mercurial preparations (mercuric chloride 1 to 1000, tincture of merthiolate and 0.1 per cent solution of merthiolate) failed to exert a rapid disinfection of the skin. Chlorox (10 per cent solution of chlorine in water), either in 70 per cent ethyl alcohol or in aqueous solution, also proved to be less successful, as did dettol. Similarly, petrol, acetone, propyl alcohol, brilliant green and crystal violet, 1 per cent of each of these substances in 75 per cent methylated spirit, revealed a slower or an otherwise imperfect disinfecting power.

DAVID H. LYNN, M.D.

The Results of the Systemic Administration of the Antibiotic, Bacitracin, in Surgical Infections FRANK L. MELENEY, WILLIAM A. ALTEMEIER, ALFRED B. LONGACRE, EDWIN J. PULASKI, and HAROLD A. ZINTEL *Ann. Surg.*, 1948, 128 714

The authors have presented the results of the systemic administration of bacitracin in 105 cases of surgical infections and have discussed the various advantages and disadvantages of the new antibiotic.

Bacitracin has a wide antibacterial spectrum, being effective against most strains of hemolytic streptococci, nonhemolytic streptococci, coagulase-positive staphylococci, pneumococci, gonococci, anaerobic cocci in general, all of the gas gangrene group of organisms and the bacillus of tetanus, the diphtheria bacillus and diphtheroids, the spirochetes of syphilis and mouth spirochetes, the actinomycotic group of organisms, and, among the protozoans, the *Endamoeba histolytica*. There is little or no action against the large group of aerobic gram-negative nonspore-forming bacilli.

The chief advantages that bacitracin has over penicillin are that (1) it is not inhibited by the organisms which produce penicillinase and is, therefore, more likely to be effective in infections due to bacterial mixtures, (2) it is more slowly eliminated from the body and, therefore, can be given at longer intervals, (3) its effectiveness against bacteria is in direct proportion to its concentration, (4) so far, bacitracin has shown less tendency to produce allergic or hypersensitive reactions but these may come with its more extended use.

Its chief disadvantage, as compared with penicillin, is that it has not yet been obtained in a pure or crystalline form and, in the present state of its impurity, it produces, when injected systemically in man, certain evidences of nephrotoxicity which limits its dosage and the duration of treatment.

Its chief advantages over streptomycin are its wider antibacterial spectrum, particularly with regard to the anaerobic organisms, and the low order of the development of resistance during the course of treatment. Its chief disadvantage with respect to streptomycin is its ineffectiveness against the gram-negative aerobic nonspore-forming bacilli.

While bacitracin is not inactivated by gastric acidity or by the proteolytic ferments of the gastrointestinal tract, it is not absorbed to any extent from the alimentary canal. There is a possibility that it may be combined with streptomycin or some of the relatively insoluble sulfonamides to minimize the activity of the intestinal flora before surgical procedures on the bowel. Bacitracin has been found effective in a few cases of intestinal infections, namely, in chronic ulcerative colitis and regional ileitis. Encouraging results are obtained by mouth administration in both the acute and chronic stages of amebic dysentery.

The information compiled in this study includes 105 cases of surgical infections observed in various units set up for the appraisal of bacitracin. Information was gathered with regard to various types of surgical infections, which includes diagnosis and duration (30 days having been set as the dividing line between acute and chronic infections), a record of previous treatment, if any, both local and systemic, the general status of the patient as indicated

ANESTHESIA

Indication for Anesthesia and Mode of Introduction of the Anesthetic for Amputation of the Tongue (Indicação da anestesia e via de introdução do agente anestésico na amputação de língua)
CARLOS A CABRAL DE MENEZES *Rev brasil cir*, 1948, 17 61

For humanitarian reasons, local anesthesia should not be employed for extirpation of the tongue. Intravenous anesthesia is also contraindicated because it does not abolish certain reflexes in the operative field and because it may provoke a vasovagal reflex leading to a cardiac syncope. Rectal avertin anesthesia is difficult to control and is undesirable because of the respiratory depression.

General anesthesia with intratracheal intubation is the method of choice. The nasal route should be used because it does not obstruct the operative field. Sponges placed in the pharynx prevent the entry of foreign material between the cannula and the wall of the trachea.

If the tumor occupies the base of the tongue and thus interferes with the introduction of the intratracheal tube, the latter can be placed in the proper position through an upper tracheotomy. This method was successfully used by the author in one patient.

JOSEPH K. NARAT, M.D.

Anesthesia for Thoracoplasty: The Use of a Pentothal-Curare Mixture Supplemented with Nitrous Oxide-Oxygen Preliminary Report EM-METT W. GREIF, RALPH C. RICHARDS, and F. A. DUNCAN ALEXANDER. *Anesthesiology*, 1948, 9 637

The requisites of satisfactory anesthesia for thoracoplasty include adequate exchange of respiratory gases, smooth induction with quiet respiration, early recovery of an effective cough mechanism, minimal postanesthetic complications, and provision for facile intubation and tracheobronchial aspiration. A method by which these requisites have been largely attained, through the employment of the intravenous administration of a solution of pentothal sodium mixed with d-tubocurarine, is described. Nitrous oxide and oxygen mixtures are administered by inhalation as a supplement.

Advantageous results are reported following the use of this method in 127 consecutive operations performed upon 55 patients. The necessity for diligent vigilance in the successful employment of this method is emphasized. Patients of this type usually have a diminished respiratory reserve and it is essential that they be protected from the potentially depressant qualities of this combination of drugs.

MARY FRANCES POE, M.D.

Hypobaric Pontocaine Spinal Anesthesia for Exploration for Extruded Nucleus Pulposus P. C. LUND. *Current Res Anesth*, 1948, 27 301

A method of exploration for extruded nucleus pulposus is described. The method is referred to as the prone technique. Hypobaric pontocaine solution

by the blood count, sedimentation rate, and kidney function, including the tests for nonprotein nitrogen or blood urea nitrogen, clearance of phenolsulfonphthalein, and the presence of albumin, sugar, casts, and cellular elements, the dosage of bacitracin, both systemic and local, the symptoms and signs of infection before and during treatment, the time relationship of any surgical procedure, the blood levels, the percentage of bacitracin excreted in the urine, a complete bacteriologic analysis of the infection before, during, and after treatment and the results obtained.

It was hoped by these investigators that the value of bacitracin could be demonstrated in those cases in which the antibiotic was superior to other forms of treatment.

The results obtained by the systemic administration of the new antibiotic, for the most part in those patients who had failed to respond to the sulfonamides and to the other antibiotics, revealed a wide diversity of conditions.

There was an overall favorable response in about 70 per cent of these cases, and in about one-fifth of them the results were dramatic.

Three cases of extensive progressive bacterial synergistic gangrene were of particular interest in that these patients responded within 72 hours and recovered without the necessity for surgical excision. In the three largest groups of patients, namely, the "cellulitis," "deep abscess," and "infected accidental wound" groups, favorable results were obtained in 78 per cent of the cases.

In the group with dramatic results, the causative organisms were for the most part in the staphylococcal and streptococcal groups. In the latter classification were found hemolytic, nonhemolytic, microaerophilic and anaerobic streptococci. In a considerable number of staphylococcal strains, the authors found a resistance to penicillin and a susceptibility to bacitracin.

In 14 per cent of the cases the results were questionable, and in a slightly higher percentage the results were frankly nil. In most of these cases the causative organisms were resistant to bacitracin.

In the majority of the patients studied in the whole series, there was a transient albuminuria which disappeared either during continued treatment or soon after treatment was discontinued.

Some of the later preparations of bacitracin have shown evidence of nephrotoxicity. Thus, the authors have suggested that when the presently available bacitracin is used systemically, there should be repeated tests for dysfunction of the kidney, and treatment should be discontinued if there is any indication of serious damage.

However, with doses which are not damaging to the kidneys, favorable and sometimes dramatic results should be expected in surgical infections caused by organisms which are susceptible to bacitracin. As has been indicated, these organisms include a wide range of bacteria and are commonly found in surgical infections.

by the blood count, sedimentation rate, and kidney function, including the tests for nonprotein nitrogen or blood urea nitrogen, clearance of phenolsulfonphthalein, and the presence of albumin, sugar, casts, and cellular elements, the dosage of bacitracin, both systemic and local, the symptoms and signs of infection before and during treatment, the time relationship of any surgical procedure, the blood levels, the percentage of bacitracin excreted in the urine, a complete bacteriologic analysis of the infection before, during, and after treatment and the results obtained

It was hoped by these investigators that the value of bacitracin could be demonstrated in those cases in which the antibiotic was superior to other forms of treatment

The results obtained by the systemic administration of the new antibiotic, for the most part in those patients who had failed to respond to the sulfonamides and to the other antibiotics, revealed a wide diversity of conditions

There was an overall favorable response in about 70 per cent of these cases, and in about one-fifth of them the results were dramatic

Three cases of extensive progressive bacterial synergistic gangrene were of particular interest in that these patients responded within 72 hours and recovered without the necessity for surgical excision

In the three largest groups of patients, namely, the "cellulitis," "deep abscess," and "infected accidental wound" groups, favorable results were obtained in 78 per cent of the cases

In the group with dramatic results, the causative organisms were for the most part in the staphylococcal and streptococcal groups. In the latter classification were found hemolytic, nonhemolytic, microaerophilic and anaerobic streptococci. In a considerable number of staphylococcal strains, the authors found a resistance to penicillin and a susceptibility to bacitracin

In 14 per cent of the cases the results were questionable, and in a slightly higher percentage the results were frankly nil. In most of these cases the causative organisms were resistant to bacitracin

In the majority of the patients studied in the whole series, there was a transient albuminuria which disappeared either during continued treatment or soon after treatment was discontinued

Some of the later preparations of bacitracin have shown evidence of nephrotoxicity. Thus, the authors have suggested that when the presently available bacitracin is used systemically, there should be repeated tests for dysfunction of the kidney, and treatment should be discontinued if there is any indication of serious damage

However, with doses which are not damaging to the kidneys, favorable and sometimes dramatic results should be expected in surgical infections caused by organisms which are susceptible to bacitracin. As has been indicated, these organisms include a wide range of bacteria and are commonly found in surgical infections

JOHN E. KARABIN, M.D.

ANESTHESIA

Indication for Anesthesia and Mode of Introduction of the Anesthetic for Amputation of the Tongue (Indicação da anestesia e via de introdução do agente anestésico na amputação de língua)
CARLOS A. CABRAL DE MENEZES *Rev. brasil. cir.*, 1948, 17, 61

For humanitarian reasons, local anesthesia should not be employed for extirpation of the tongue. Intravenous anesthesia is also contraindicated because it does not abolish certain reflexes in the operative field and because it may provoke a vasovagal reflex leading to a cardiac syncope. Rectal avertin anesthesia is difficult to control and is undesirable because of the respiratory depression.

General anesthesia with intratracheal intubation is the method of choice. The nasal route should be used because it does not obstruct the operative field. Sponges placed in the pharynx prevent the entry of foreign material between the cannula and the wall of the trachea.

If the tumor occupies the base of the tongue and thus interferes with the introduction of the intratracheal tube, the latter can be placed in the proper position through an upper tracheotomy. This method was successfully used by the author in one patient.

JOSEPH K. NARAT, M.D.

Anesthesia for Thoracoplasty. The Use of a Pentothal-Curare Mixture Supplemented with Nitrous Oxide-Oxygen. Preliminary Report. EMMETT W. GREIF, RALPH C. RICHARDS, and F. A. DUNCAN ALEXANDER *Anesthesiology*, 1948, 9, 637

The requisites of satisfactory anesthesia for thoracoplasty include adequate exchange of respiratory gases, smooth induction with quiet respiration, early recovery of an effective cough mechanism, minimal postanesthetic complications, and provision for facile intubation and tracheobronchial aspiration. A method by which these requisites have been largely attained, through the employment of the intravenous administration of a solution of pentothal sodium mixed with d-tubocurarine, is described. Nitrous oxide and oxygen mixtures are administered by inhalation as a supplement.

Advantageous results are reported following the use of this method in 127 consecutive operations performed upon 55 patients. The necessity for diligent vigilance in the successful employment of this method is emphasized. Patients of this type usually have a diminished respiratory reserve and it is essential that they be protected from the potentially depressant qualities of this combination of drugs.

MARY FRANCES POE, M.D.

Hypobaric Pontocaine Spinal Anesthesia for Exploration for Extruded Nucleus Pulposus. P. C. LUND *Current Res. Anesth.*, 1948, 27, 301

A method of exploration for extruded nucleus pulposus is described. The method is referred to as the prone technique. Hypobaric pontocaine solution

is used in a 0.1 per cent concentration, with or without the addition of epinephrine, in a 1 to 11,000 to 1 to 21,000 concentration. It is believed that pontocaine, when given in dilute solution, is relatively non-toxic and possesses physical properties which accurately control its spread within the subarachnoid space. The anesthetic is prepared by dissolving the pontocaine hydrochloride crystals (niphonoid) in distilled water. The pH of this solution is 5.6 and its specific gravity at 37 degrees is 1.003 and at 45 degrees is 1.001. It produces maximum sensory analgesia with minimum anterior motor block.

With the patient placed in a prone position, the needle was introduced into the subarachnoid space and from 7 to 15 c.c. (average, 10 c.c.) of the 0.1 per cent pontocaine solution was injected. To this was added epinephrine in a 1 to 11,000 concentration, which combination gave satisfactory anesthesia for a period of 3 to 4 hours or more.

A noteworthy feature of spinal anesthesia induced with the smaller doses of hypobaric pontocaine was that tension produced by the surgeon on a nerve root often gave rise to pain over this area of distribution. This often aided in the location of pain similar in character and distribution to the pain complained of preoperatively. In the series of 135 patients treated in this manner there were no severe complications or sequelae directly attributable to the method.

MARY KARP, M.D.

Spinal Epidural Block ELIAS D. LAWRENCE *Anesthesiology*, 1948, 9: 601

Epidural block is a valuable method of anesthesia that has been neglected in this country because of an incorrect impression of its difficulties and dangers. The author hopes that the present article will stimulate an interest in the use of this block for the relief of pain. His work confirms previous reports that there is no negative pressure in the epidural space. He reviews the essential anatomy of this space and describes a technique for performing epidural block. The apparatus includes a special needle which has a large bore and a blunt bevel point.

MARY FRANCES POE, M.D.

The Problem of Anesthesia in Switzerland (Le problème de l'anesthésie en Suisse) P. DECKER *Helvet. chir. acta*, 1948, 15: 423

There is no doubt that, in the matter of inhalation anesthesia, the Anglo-American surgical clinics are much more advanced than most of the clinics of continental Europe, and some of the most important developments of surgery during the past few years are connected with the progress of inhalation anesthesia made in the Anglo-American countries. The reason for this superiority lies in the fact that in those coun-

tries the anesthetics have long since been performed by specialists who devote all of their time to this work. Some are licensed physician anesthetists, but the greatest number are specially trained nurses. In Switzerland there are no such specialists and it would take a long time to develop them. In addition, there is another problem: whereas in the large clinics of England and America a constant stream of operations are going on throughout the day, in Switzerland nearly all operations both at the hospital and in town are performed in the morning, with the result that if a specialized anesthetist would work at the hospital, the modest salary which he would receive would not amount to a living, and if he would work in town the hospital services would be without an anesthetist. Undoubtedly a few specialists would be able to earn a living in the largest cities, but this would not solve the problem of modern anesthesia for the country at large.

In continental Europe the surgeons have developed, to the limit, local anesthesia which is non-toxic and nonasphyxiating, yet allows long operations. Local or regional anesthesia and inhalation anesthesia each have their advantages and their indications; those of local anesthesia are numerous.

With regard to inhalation anesthesia, if the intervention is short in a subject who is in good health and whose respiratory apparatus remains outside the operative field, the procedures used up until the present in Europe—semi-closed ether and even chloroform—can still be utilized without inconvenience to the patient. Nitrous oxide is excellent for induction, but also for the complete operation if it is not too long (from 1 to 2 hours), if respiration is not impeded, and if the circulation is not deficient. For the remainder of surgery, including all chest operations with open pleura, closed circuit ether-oxygen anesthesia, with or without an intratracheal tube, is believed to be sufficient and is the least dangerous for the patient.

Local anesthesia may be carried out by the surgeon's assistants who may also attend to semi-closed ether anesthesia, but nitrous oxide and closed circuit ether, with or without an intratracheal tube, must be administered by specialized anesthetists. The author believes that intelligent nurses who are well trained and have the necessary character for the work could administer anesthetics as well as some anesthesiologists who are scientists rather than practicing anesthetists; consequently it is not necessary to reorganize completely the anesthetic services to enable Swiss surgeons to apply, under favorable conditions, their newly acquired surgical knowledge. On the other hand, the use of cyclopropane and curare must be left to physicians.

RICHARD KEMEL, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Rotary Kymography at 100 Revolutions (La kimo grafía rotatoria a centros múltiples, dos años de vida de mi método kimográfico) MARIO LENZI *Radio logía, B Air, 1947, 10 83*

Lenzi describes his method of kymography and the results obtained after a number of years' study in this type of work. It is possible to outline the contour of the heart with mathematical precision, as well as other moving organs of the body. This would include the diaphragm, stomach, aneurysms, pulmonary cavities, and the like. The method employed requires considerable knowledge of mathematics and physics, hence the ordinary practitioner or roentgenologist will find considerable difficulty in obtaining exact quantitative measurements. The basic principle of the machine is founded on a rotary grill, the speed of which is known as well as the distances between the radiant spokes.

STEPHEN A. ZIEMAN, M.D.

Diagnosis of Pulmonary Stenosis by Angiocardiography MERL J. CARSON, THOMAS H. BURFORD, WENDELL G. SCOTT, and JAMES GOODFRIEND *J. Pediat., S. Louis, 1948, 33 525*

The authors have found angiocardiography of considerable aid in establishing, more exactly, the diagnosis in several types of congenital cardiac anomalies, and of particular value in differentiating the various types in which cyanosis is a prominent symptom. The method has proved applicable to patients of all ages, including infants and children so small that cardiac catheterization is impractical.

An autograph capable of making 10 radiographic exposures within 10 seconds is used. The patients are fasted for 4 hours before the procedure, but those with cyanosis and polycythemia receive subcutaneous fluids preoperatively to prevent dehydration, and are given oxygen during the period of anesthesia. Infants and very young children receive general ether anesthesia, for older patients, local novocain is sufficient.

An antecubital vein is cannulated after ligation of its distal portion. Patency is assured by a slow saline drip, and then a few drops of 70 per cent diodrast are injected through the cannula. If within several minutes no reaction has occurred, the final injection is made, i.e., from 10 to 18 c.c. of the contrast medium for infants 3 to 24 months of age, 20 to 30 c.c. for children of 2 to 10 years of age, and 30 to 40 c.c. for children between 11 and 15 years of age. The injection period should not be longer than 2 seconds, and injection should be begun immediately after the first roentgen exposure. The rest of the series of roentgenograms is made in quick succession during and immediately after the injection of diodrast.

The authors find the left anterior oblique and the anteroposterior views to be the two most useful views, and their article is accompanied by an excellent sequence of films of the normal in each position. The particular advantage of the oblique view over the frontal view is that in the former the shadows of the pulmonary arteries are separated from those of the aorta, such separation being essential in the types of cardiac abnormality in which the pulmonary artery and aorta fill simultaneously.

Angiocardiograms of 4 cases are presented, to illustrate the value of the method in differentiating various types of cyanotic congenital heart disease. Included are a nonfunctioning right ventricle with tricuspid stenosis, persistent truncus arteriosus, the tetralogy of Fallot, and the Eisenmenger complex. Autopsy proof cannot be offered, but 2 of the cases were explored surgically.

The electrocardiogram of a 1 year old cyanotic infant showed right axis deviation, and plain roentgenograms revealed decreased pulmonary ventricular markings, enlargement of the right ventricular salient, slight concavity of the region of the pulmonary conus, and a clear aortic window. A tentative diagnosis of the tetralogy of Fallot was made and confirmatory evidence was sought in the angiocardiograms. These revealed early filling of the left ventricle, which was believed indicative of an interventricular septal defect, small pulmonary conus, very small pulmonary arteries, and simultaneous filling of pulmonary arteries and aorta, suggestive of an overriding aorta. At operation there was evidence of pulmonary stenosis. It is pointed out that the decreased caliber of the pulmonary arteries in itself allows differentiation of the tetralogy of Fallot from Eisenmenger's complex, for in the latter condition the angiogram shows the pulmonary arteries to be of normal or increased size.

Angiocardiograms of a 16 months old cyanotic infant with cardiac enlargement showed the diodrast entering successively the superior vena cava, the right auricle and a very large right ventricle, from whence it appeared to spill over into the left ventricle, and visualized the beginning of a large common arterial pathway from which very small pulmonary arteries appeared to arise. These findings were interpreted as being those of an interventricular septal defect with persistent truncus arteriosus.

The remaining case was that of a cyanotic infant of 14 months in whom the opaque material failed to flow into the expected region of the right ventricle, and instead appeared to pass directly from the right to the left auricle and then into the enlarged left ventricle. Both the normal sized aorta and the small pulmonary conus appeared to come off the left ventricle and to fill simultaneously. It was concluded that the right ventricle was either absent or occluded from the circulation by an atretic tricuspid valve. At opera-

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Traumatic Shock and Curare (Squasso traumatico e curaro) L IMPERATI, G D'ERRICO, and A RUGIERO *Gior ital chir*, 1948, 4 635

The authors studied the effects of curare on 10 rabbits and recorded the results in each experiment. Their objective was to determine the results produced upon the circulatory system and upon the blood concentration. From these experiments they derived the following practical information:

- 1 There is a great variability of individual tolerance to tubocurarine (Tubarine-Wellcome)

- 2 Through individual hypersensitivity, high dosage, or rapid administration, there can be produced a state of shock which may be severe enough to cause death, or other phenomena of severe central irritation resulting in convulsions and cardiac damage

- 3 In the majority of cases this drug can be given without any great repercussions, either hemodynamic or humoral

- 4 Curare must be given with great precaution as errors may cause very grave accidents

The authors recommend that curare should be given slowly and in small doses. Large doses or rapid administration of regular doses may be followed by central nervous phenomena manifested by tonic-clonic convulsions or by shock with drop in blood pressure accompanied by hemoconcentration and hyperproteinemia.

LUCIAN J FRONDUTI, M D

Experimental Study of Wound Healing. A New Technique and a Study of the Effect of Detergents and of an Antacid on Wound Healing S SCHEINBERG, S P BRALOW, and H NECHELES *Surgery*, 1948, 24 972

The authors devised a technique for studying wound healing by observing a standard punch-inflicted wound through a covering of transparent x-ray film supported by a lucite ring and sealed with methacrylate polymer solution. The guinea pig was the experimental animal and the authors believed that contraction of the wound was prevented by their technique.

Wound healing is expressed as the size of the healed area in per cent of the original wound. Some confusion arises since the tables are headed "Percentage Rate of Healing" but the conclusions drawn indicate that percentage of healing rather than percentage rate of healing is represented.

The experiment was designed to test the effect of detergents on wound healing—sodium lauryl sulfate (Dreft), tetramethylammonium-hydroxide (Triton NE), and alkyl-dimethyl-benzyl-ammonium-chloride (Zephiran) being used. Methylcellulose was used

as a base because of its low absorbability and its transparency which tended to make observation of the wounds easier. A control on methylcellulose showed no statistically significant effect on wound healing.

In addition, one antacid (sodium carboxymethylcellulose) was tested alone and in combination with magnesium oxide, sodium bicarbonate, and sodium lauryl sulfate.

Variations in body weight, red cell count, hemoglobin, and total proteins, as well as low grade wound infections were found to be insignificant in their effect on wound healing as they occurred normally within the limits of this experiment.

The results of the experiment indicate a statistically significant improvement in healing with (1) 1 per cent sodium lauryl sulfate in methylcellulose, (2) 2 per cent sodium lauryl sulfate in methylcellulose, (3) sodium carboxymethylcellulose alone or in combination.

The authors do not draw conclusions concerning the specific reasons for the effects observed, and point out that the detergent action, the alkaline pH, and the presence of a good supporting base are at least factors which might be of importance.

JOHN H KAY, M D

Infection. A Hospital Problem SYDNEY D RUBBO *Med J Australia*, 1948, 2 627

A comparison is drawn between problems of infection in the hospital during the nineteenth century and those during the twentieth century.

Progress in surgery and obstetrics is shown to be due in part to the assimilation of the germ theory of disease.

The work of Lister and of Semmelweis on antiseptic treatment is briefly reviewed.

The importance of asepsis is stressed and the principles underlying this practice are defined.

The problem of infection in the hospital today is illustrated by an analysis of postoperative wound infections in 253 cases of radical mastectomy and by a brief description of an outbreak in the hospital of gastroenteritis due to *Salmonella* derby.

The problem of control of infection in the hospital is discussed under the following headings: the control of primary and secondary reservoir of infection, the use of physical and mechanical barriers against spread of infection, the development of increased host resistance by chemoprophylaxis and immunoprophylaxis.

An indication is given of how detection of carriers of infection should be incorporated into routine hospital practice.

A dressing technique applicable to surgical wards is described.

Oiling of floors and bedclothes is demonstrated as a most effective means of dust control.

The use of electrostatic air filtration and positive pressure ventilation for dressing stations and operating theaters is recommended. The importance of masking as a means of controlling droplet infection is stressed. Other methods of droplet control, such as barrier nursing and the use of ultraviolet light and of aerosol sprays, are briefly discussed. The use of mild antiseptics in dressing noninfected wounds at the time of operation is recommended as a prophylactic measure. Bacillus Calmette Guérin vaccination of nurses and patients who fail to react to tuberculin, and diphtheria immunization of susceptible children whose stay in the hospital will be longer than 6 weeks, is suggested. Blood transfusion for puerperal patients suffering from anemia (hemoglobin value of less than 70 per cent) as a prophylaxis against anaerobic streptococcal infection is recommended.

JOHN J. MALONEY, M D

Air Infection with Dust Liberated from Clothing
J P DUGUID and A T WALLACE *Lancet*, Lond., 1948, 2 845

The present study concerns itself with measuring the bacterial contamination of air produced by liberation of dust from the skin and personal clothing during bodily movement, the duration of air carriage of the bacteria-carrying dust particles, and the effectiveness of gowning as a means of preventing such contamination of air.

The tests were carried out in a specially constructed chamber from which air was withdrawn by a short tube through the wall to a slit sampler outside for bacteriologic examination. The samples were placed on either ordinary blood agar or heated blood agar. Four healthy men were used for the principal experiments, these being subjected to the following standard activities within the chamber: standing motionless, slight activity, vigorous activity, undressing and dressing and brushing clothes. Seventeen experiments were performed with each subject. Large numbers of bacteria-carrying dust particles were liberated by even slight activity and the number increased considerably as the activity became more vigorous. Some 10 per cent of these bacteria-carrying dust particles remained air-borne for over half an hour. Observations with two nasal carriers of *Staphylococcus* showed that the air was infected with this pathogenic organism more regularly, and to a greater degree, by the liberation of dust from clothing than by sneezing. *Staphylococcus aureus* was present in about 0.1 per cent of the bacteria-carrying dust particles which entered the air from the clothing or carriers.

Air contamination with dust-borne bacteria from clothing reduced only a little (to about half) when the usual surgical type of sterile loose cotton gown was worn over ordinary clothing. However, when a sterile dustproof gown was employed, contamination was reduced to a tenth or a twentieth. Hence, under

ordinary circumstances, dissemination of infection from the respiratory tract via clothing dust to the air constitutes a means whereby surgical aseptic technique may be breached.

DAVID H. LYNN, M D

Plaster of Paris as Source of Infection in Tetanus and Gas Gangrene E G D MURRAY and G D DENTON *Canad M Ass J*, 1949, 60 1

This is the first of three articles published simultaneously in the Canadian Medical Association Journal, dealing with the potential hazard of plaster of Paris as an agent in the contamination of wounds with the organisms of tetanus and gas gangrene. The authors report one fatal case of tetanus which followed an elective arthrodesis of a tuberculous knee.

Two and one-half weeks after operation and the application of a long leg cast, the wound was seen to be infected, but no bacteriological study was made. On the thirtieth postoperative day signs and symptoms of tetanus were recognized, and the wound exudate was studied. *Clostridium tetani* was found, together with *Pseudomonas aeruginosa*, *Aerobacter aerogenes*, and an anaerobic streptococcus. The patient died the next day. The strain of *Clostridium tetani* isolated antemortem was completely characteristic. It produced fatal tetanus in a guinea pig not protected by antitetanus serum but did not affect a protected animal. Postmortem material from the wound yielded a growth of *Clostridium tetani*, *Clostridium perfringens*, and *Pseudomonas aeruginosa*. The specimen removed from the knee at the original operation had yielded only *Mycobacterium tuberculosis*.

A thorough search for a source of contamination threw suspicion on the plaster. Unfortunately both casts worn by the patient had been discarded, and the supply of bandages from which these casts had been made had been exhausted. Two newer bandages of the same manufacture were examined and both were found to contain clostridial organisms, one *Clostridium tetani*. This organism was recovered from a piece of the second bandage which contained only two square inches of material. Twenty-eight other bandages representative of batches made in 1945, 1946, 1947, and 1948 were examined by culture of the whole roll. All but one of these specimens exhibited anaerobes, usually in combination with pathogenic aerobes. *Clostridium welchii* was found in 24 of the bandages.

Experiments with the sterilization of plaster bandages indicated that single rolls could be sterilized by heating to 200 degrees C for a period of 5 minutes. When the rolls were heated in their original containers, 6 bandages to the package, this temperature had to be maintained for 2 hours to kill all organisms. Autoclaving was found to be unsatisfactory because moisture spoils the plaster. Dry heat for more than 2 hours at 200 degrees C was found to destroy the fabric of the bandage.

The authors conclude that until only recently the serious infective potentialities of plaster of Paris

have not been properly appreciated or guarded against

BENJAMIN F LOUNSBURY, M D

Chronic Progressive Infectious Gangrene of the Skin F A SIMEONE and H. L. HARDY *Ann Surg*, 1948, 128 1112

The authors' report concerns a 33 year old hair-dresser who for 2 years had shown signs of unusual susceptibility to infection. She was admitted to the hospital for treatment of a large gangrenous external hemorrhoid and a blisterlike pustule on the leg. Subsequently she developed a similar blister in a broad right paramedian abdominal scar. Both blisters broke spontaneously. The one on the leg healed, that in the abdominal scar left an ulceration which spread progressively until the surface of the entire scar and another abdominal scar sloughed away. Among the numerous laboratory examinations, only 2 were of positive interest, namely, the increased sedimentation rate and a leucopenia without agranulocytosis. The patient was acutely ill with a severe general systemic reaction. No pus could be obtained from any of the ulcerated nodules. A culture from one of the ulcerated areas showed *Escherichia coli*, *Staphylococcus aureus*, and alpha-hemolytic streptococci. A block excision of involved skin was done after the lesion had failed to respond to conservative therapy, with an immediate improvement in the patient's condition. Split-thickness skin grafts were applied to the granulating area and healing was obtained.

Because of the peculiar hematologic response and impaired liver function, it was suspected that there was a factor of intoxication in this case. The only possibility that could be disclosed was the presence of thioglycolic acid or thioglycolates in "cold wave" solutions which the woman handled in her work. The possible relationship between the manifestations of the infection and exposure to these substances is discussed.

JOHN L. LINDQUIST, M D

The Effects of Streptomycin on the Eighth Nerve System M R DIX *J Lar Otol*, Lond, 1948, 62 735

The author's observations confirm the results of Brown and Hinshaw (1946), Fowler and Seligman (1947), Glorig and Fowler (1947), that streptomycin has a selective toxic action upon the vestibular apparatus. The precise locus of this action remains obscure.

JOHN J. MALONEY, M D

The Frontiers of Banti's Disease (Les frontières de la maladie de Banti) EMILE HOUCKE *Bruxelles méd*, 1948, 28 2657

The author discusses the symptomatology, etiology, pathology, and treatment of Banti's disease. He believes, and offers pathological findings, that Banti's disease may have many causes, including syphilis and tuberculosis. The disease is the result of an alteration in the reticuloendothelial system of

the spleen primarily, and secondarily involves the liver. The causes inciting this change are multiple but the response of the reticuloendothelial system is constant. The author's pathological criteria for the diagnosis include diminution of the malpighian corpuscles, sclerosis of the central artery of the follicle, hypertrophy of the reticulum, and atrophy of the sinuses of the spleen. Cirrhosis of the liver develops slowly, is less intense, and is reversible if splenectomy is done early in the disease. In 1 patient splenectomy caused a complete regression of the liver sclerosis with ascites.

Although Banti considered this disease as affecting only the young, the author believes that older individuals are frequently afflicted. He states that the peripheral blood picture is inconstant and never absolutely diagnostic, but that leucopenia, thrombocytopenia, and anemia usually occur.

He considers splenectomy the treatment of choice and believes that a complete cure will result if this procedure is accomplished early in the disease.

JOHN H. FLYNN, M D

Carcinoma Developing in Sebaceous Cysts JOSEPH C PEDEN, JR. *Ann Surg*, 1948, 128 1136

Microscopic studies of 832 surgically removed sebaceous cysts revealed 14 cases of carcinoma, an incidence of 1.7 per cent. In 5 cases histologic evidence of the origin of carcinoma in the sebaceous cysts was not conclusive so that other evidence of such origin was taken into consideration. The average age of the patients was 51.6 years.

The relatively low incidence of carcinoma in sebaceous cysts does not justify considering sebaceous cyst as a precancerous lesion. However, in older patients who have had a sebaceous cyst of long duration on the face or scalp, perhaps ulcerated, and in which a recent change in character, such as an increase in size, has been observed, carcinoma should be suspected. The most common type of cancer found in sebaceous cysts is a well differentiated squamous cell carcinoma of low grade malignancy, and usually these have not metastasized when first seen. Basal cell carcinomas occur much less frequently.

Sebaceous cysts which are suspected of fostering carcinoma should be treated by wide local excision. Immediate lymph node dissection is not generally necessary, although markedly anaplastic growths may justify such a procedure. Evidence of lymph node metastasis subsequent to previous local excision should be treated by block removal of the nodes.

With adequate treatment the prognosis is good. Ten of 11 patients with adequate follow up treatment have been cured. The one uncured patient had unresectable lymph node metastasis. Routine histologic examination of all sebaceous cysts removed is advocated.

NUMBER 3

LATE RESULTS IN TREATMENT OF PANCREATIC CYSTS BY INTERNAL DRAINAGE

DAVID HENRY POER, M D, F A C S, and ROBERT H STEPHENSON, M D,
Atlanta, Georgia

PANCREATIC cysts are encountered so infrequently in the clinical experience of any one surgeon that the question of treatment of such a lesion when it presents may pose a problem of difficult decision. The diverse etiology, association with acute and chronic pancreatitis and biliary pathology, and the tendency to drain for long periods and to recur, all serve to complicate any outline of treatment. The purpose of this paper is to consider briefly the classification, etiology, diagnosis, and treatment of cysts of the pancreas, and to report 3 cases, 2 of which have been observed for a period of 7 to 8 years, following internal drainage.

CLASSIFICATION

In the literature one may find many classifications of pancreatic cysts (11, 20, 21). The classification used by Mahorner and Mattson (15, 12) is one of the best.

- 1 Cysts due to defective development
 - a In infants
 - b Associated with polycystic disease of kidneys
 - c Dermoid cysts
 - d Inclusion
- 2 Cysts due to trauma
- 3 Retention cysts

- 4 Neoplastic cysts
 - a Cystadenoma
 - b Cystadenocarcinoma
 - c Teratoma
- 5 Cysts due to parasites

Cysts are spoken of as true cysts and pseudocysts. The former term implies those with a lining completely formed by epithelium or by pancreatic tissue. The pseudocysts, which are predominately formed by trauma, vascular or degenerative changes, frequently do not lie entirely within the pancreas, but are located within the lesser peritoneal sac, between the stomach and liver or between the leaves of the mesocolon. Practically speaking, it is frequently impossible to distinguish at operation between true and pseudocysts, as the former may lose their epithelial lining after some time, and present the appearance of a pseudocyst.

Pancreatic abscesses or collections, as Pinkham prefers to call them, may also present a differential diagnostic problem, as these may result from the same factor as pseudocysts. Here the rapidity of appearance, plus signs of infection, helps to distinguish them. This group of pancreatic collections might well form a sixth group in the classification scheme presented, as being due to acute and chronic pancreatitis, pancreatolithiasis with infection, and concurrent biliary disease.

From the Whitehead Department of Surgery, Emory University, Georgia, and the Surgical Services, Grady Memorial Hospital, Atlanta, Georgia.

ETIOLOGY

In their article in 1931, Mahorner and Mattson considered in some detail the etiology and pathology of pancreatic cysts (15, 12). In general, their discussion follows closely the classification given by them.

Probably the most common cyst is the simple retention type, which is frequently an incidental finding at necropsy (16). These are small, may be multiple and result from the occlusion of a duct or several acinar openings, by fibrosis, inflammation, or neoplastic changes (4). Occasionally, pancreatic calculi are found in association with these (17).

Cysts which result from defective development are rare, and may be seen in children and infants with other congenital anomalies, such as polycystic kidneys and congenital heart disease. Dermoid and inclusion cysts may be included in this category.

Neoplastic change in the pancreas can produce cystic degeneration by occlusion of main ducts or smaller branches. In cystadenocarcinoma, new cysts may be formed by acinar proliferation and secretion. This is rather unusual, however, since most pancreatic tumors present as solid growths.

The production of cysts of the pancreas by parasites is rare, and is due to encystment of the organisms or blockage of the duct system.

A history of trauma is elicited in a significant number of pancreatic cysts (2, 12, 15, 21, 22). This need not be severe, or recent, and may follow minor blows and inconsequential abdominal injury. The pancreas, a relatively immobile abdominal organ, is caught between the force applied to the abdomen anteriorly and the spine posteriorly, with resulting laceration, contusion, or hemorrhage. Almost all cysts resulting from trauma are pseudocysts, with a portion of their wall being formed by the lesser peritoneal sac or mesocolon.

A mass may present early or late trauma. The insignificant amount of trauma required may be forgotten by the patient and the appearance of the cyst be considered as without due cause. The pathologic changes which occur may be hemorrhage with later degeneration, autolysis by pancreatic ferments, or a combination of the two.

Recently, the role of acute and chronic pancreatitis in the pathogenesis of pancreatic cysts has been emphasized (19, 26). The processes probably account for a greater proportion of cysts than has formerly been recognized. Pinkham points out that both true and pseudocysts may be formed. The part played by degeneration, obstruction, and concurrent biliary disease are all to be considered. Each case must be individualized and the final summation of opinion may not be possible even after laparotomy.

DIAGNOSIS

The most frequent symptom of pancreatic cyst is abdominal discomfort or pain (1, 2, 5). This is experienced in the hypochondrium, epigastrium, or back, is constant in nature and of dull aching nature. The presence of pancreatitis concurrently or previously will modify to some extent the degree of pain (19).

Symptoms from pressure of the cyst on the stomach, duodenum, or colon may be noted. These take the pattern of anorexia, nausea, vague indigestion, eructations, and even vomiting. In the presence of chronic pancreatitis or biliary pathology, there may also be fatty food intolerance and signs of pancreatic or biliary insufficiency (20).

A palpable mass may be found on physical examination, is the most reliable single finding, and is almost essential for diagnosis. The mass may occupy almost any position in the upper abdomen, but is characteristically high, relatively immobile, and somewhat tense.

Roentgenologic examination (8) may demonstrate a slight opacity in the area and displacement of gas-filled organs such as the stomach, duodenum, or colon. Gastric pneumograms are especially helpful (19). Pyelography and barium enema may reveal further displacement of surrounding organs. More contributory evidence may be gained from cholecystograms revealing biliary dysfunction.

Determination of serum amylase levels may be of value in dealing with trauma, acute pancreatic degeneration, or pancreatitis. Laboratory studies may reveal mild diabetes mellitus (with abnormal glucose and insulin tolerance curves), free stool fat, and a paucity of pancreatic ferments in duodenal drainage specimens.

Fig 1 Anastomosis of pancreatic cyst to jejunum. Insert (a) depicts retrocolic anastomosis through mesocolon for cases in which stomach is displaced upward. Insert (b) shows antecolic anastomosis used when the cyst presents superiorly. In each instance, the width of the stoma is not less than 4 centimeters.

SURGICAL TREATMENT

Surgical intervention is indicated in every case of suspected or proved pancreatic cyst. Conservative management makes the patient vulnerable to possible rupture (13) into the peritoneal cavity with resultant hemorrhage, shock, or peritonitis, or internally into some portion of the gastrointestinal tract.

Three methods of surgical treatment may be employed in management (3, 5, 6): total excision which is admittedly the ideal, simple drainage by catheter or marsupialization, and internal drainage by anastomosis of the cyst to the stomach, duodenum, or jejunum.

Total excision may be possible in the case of small cysts, particularly those located in the tail of the pancreas. Excision is to be performed whenever possible because of small size or freedom from intimate involvement of surrounding structures.

Simple drainage (3, 18, 23, 24) by means of a large rubber catheter, a cigarette drain, or

marsupialization of the cyst may be employed in those cases unsuitable for excision. The specific method of drainage to be used is indicated in part by the position of the cyst and its relations to adjacent structures. Disadvantages of simple drainage are the persistence of draining fistulas, excoriation of the skin, and tendency to recur.

Internal drainage (1, 10, 14, 25) by anastomosis of the cyst wall to the stomach or small intestine will obviate the disagreeable features of external drainage and will insure adequate drainage. Although the site of anastomosis depends somewhat on the location of the cyst, the usual procedure is a cystojejunostomy with the use of two layers of sutures.

CASE REPORTS

CASE 1. P. P., aged 49 years, white male, was admitted to the Piedmont Hospital on August 5, 1946 with the chief complaint of severe epigastric pain of 30 hours' duration. The pain had begun suddenly, remained constant, and was accompanied by per-

sistent nausea and vomiting. Physical examination revealed a robust man of middle age, in acute distress. Temperature was 101 degrees F, pulse 120, blood pressure 90/60. The abdomen was slightly distended with moderate rigidity and hypoactive peristalsis. Roentgenologic examination revealed no free air in the peritoneal cavity. Diagnosis of acute pancreatitis was made, and conservative therapy instituted. After 24 hours, the abdomen became progressively more distended, pain was still present, and there was muscle spasm. Exploratory laparotomy was performed. A marked hemorrhagic necrosis of the pancreas was found, drains were placed down to the area, and the abdomen closed. Following operation, convalescence was uneventful except for transient jaundice and glycosuria. The operative wound healed by primary intention and drainage stopped on the seventeenth hospital day. He was discharged home on the twenty-first hospital day, free of symptoms.

Approximately 2 months later, on October 11, 1946, the patient was readmitted because of the appearance of an upper abdominal mass associated with nausea and vomiting. Physical examination revealed a palpable mass in the epigastrium. Pancreatic cyst was suspected, and abdominal exploration performed. Upon opening the peritoneal cavity, the pancreas presented a large cystic mass posterior to the mesocolon and below the stomach. The cyst was opened and a large amount of serosanguineous fluid and blood clots removed. The biliary tree was distended and of a deep greenish-brown color. Cholecystostomy was performed and the pancreatic cyst marsupialized. The postoperative course was uneventful and the patient was discharged home on the twentieth hospital day with drainage present from both openings.

During the ensuing 10 months he was under close observation as an outpatient. Drainage continued from both the cholecystostomy and pancreatic fistula with minimum skin irritation. Blood clots were passed intermittently, however there was no pain or gastrointestinal symptoms to indicate biliary or pancreatic dysfunction. His appetite remained good and he gained weight. An incisional hernia, noted 2 months after operation, gradually increased in size.

Eleven months after operation, drainage ceased and the fistulous tract closed. During the following year the patient remained asymptomatic, returned to work, and continued to gain weight. All laboratory studies subsequent to hospital discharge were within normal limits.

The patient was admitted to the hospital in May 1948 for further study and repair of the incisional hernia. Laboratory studies revealed a normal glucose tolerance curve. Stool examinations were negative for occult blood and free stool fat, urinalyses were negative. Oral cholecystogram revealed normal filling of the gall bladder with no evidence of stones. Ventral herniorrhaphy was performed, the wound healed well, and patient was discharged home on the fourteenth hospital day with a well healed

wound. At the time of this report he is in excellent health and asymptomatic (3 years).

CASE 2 (Patient of Dr W A Selman) G J, aged 46 years, colored female, was admitted to the Grady Memorial Hospital May 4, 1939, complaining of an upper abdominal mass of insidious onset and without previous pain or gastrointestinal upset. There was no history of abdominal disease or trauma. Physical examination revealed an obese female with no discomfort. Temperature, pulse, and respiration were normal. Blood pressure was 130/70. The abdomen was moderately obese, and there was palpable in the epigastrium a large, smooth, tense, nontender mass which appeared to be fixed posteriorly and did not move with respiration. Roentgenologic study revealed a retroperitoneal mass displacing the stomach anteriorly. A provisional diagnosis of pancreatic cyst was made and exploratory laparotomy performed. A large pancreatic cyst posterior to the stomach was marsupialized. Postoperative course was uneventful, the cyst drained well, and the patient was discharged home on the fourteenth postoperative day with a draining fistula, to be followed in the outpatient department. After draining for 3 weeks, the cyst opening closed, and no further drainage occurred. The patient remained asymptomatic until approximately 2 years later, when in August 1941, she was seen in the outpatient department, complaining of recurrence of the mass in the same location. There was a sensation of epigastric fullness, eructation, and occasional vomiting without pain. A diagnosis of recurrent pancreatic cyst was made, and re-exploration performed. The cyst was found to have reformed, and was considerably larger than on the previous operation. Because of recurrence following simple drainage, it was thought that internal drainage was indicated. Cystogastrostomy was done, in which the cyst wall was anastomosed to the posterior wall of the stomach. Postoperatively the patient's progress was good, and the cyst decreased in size. Dehiscence of the operative wound down to peritoneum occurred on the fifth postoperative day. Secondary suture was performed, and the wound healed well. The patient was discharged home on the twenty-eighth postoperative day. At this time and on follow-up a month later, she was free of gastrointestinal symptoms, was eating a regular diet, and there was no palpable abdominal mass. A small incisional hernia was present, however, at that time it was not deemed advisable to repair it.

From 1941 until November 1947, the patient was seen at irregular intervals in the surgical outpatient clinic. Repair of the incisional hernia was advised upon several occasions, but refused by the patient. There were occasional bouts of nausea and vomiting, diarrhea, and an intolerance to fatty foods. In November 1947, she was seen in the emergency clinic with nausea, vomiting, and mild abdominal pain. Examination revealed a large incisional hernia with no evidence of intestinal obstruction. She was admitted to the surgical service for study and post-

ble repair of the wound defect. Temperature, pulse, respiration, and blood pressure were normal. The patient had gained considerable weight since the last hospital admission, and the abdomen was markedly obese. A large upper abdominal incisional hernia was present, and through the defect palpation of the upper abdominal viscera was possible. No masses were felt and there was no tenderness.

Roentgenologic study of the gastrointestinal tract was entirely normal, and revealed no defect in the outline of the stomach, and no filling of the cyst through the previous cystogastrostomy. The gall bladder was not visualized by an oral cholecystogram. Laboratory studies, including glucose and insulin tolerance tests, revealed no diabetic trends. Blood studies and urinalyses were normal. Free fat was demonstrable in the stools. The serum amylase level was within normal limits. A diagnosis of chronic pancreatitis was made, and therapeutic dosage of pancreatin was given with considerable relief of symptoms. Fatty food intolerance disappeared, there was a diminution in the number of daily stools, and free stool fat was no longer demonstrable.

Herniorrhaphy was again refused and the patient was discharged home on a high protein, low fat diet, with therapeutic doses of pancreatin. During subsequent outpatient visits, and at the time of this report, she is asymptomatic.

CASE 3. C.L.C., aged 17 years, white male, was admitted to Grady Memorial Hospital on February 17, 1940, complaining of severe upper abdominal pain. Forty-eight hours before admission he had fallen across a large stone, receiving a sharp blow to his epigastrium. Nausea without vomiting developed, and there was pain on deep respiration. The patient was reported to have voided urine which was grossly bloody.

Physical examination revealed a young man in acute distress, with shallow respiration and complaining of severe abdominal pain. Temperature was 101 degrees F, pulse 90, blood pressure 140/90. The abdomen was rigid, exquisitely tender, with hypoaactive peristalsis. No masses were palpable. There was tenderness in the left costovertebral angle.

Laboratory studies revealed a white cell count of 24,000 with a neutrophilic response. Urinalysis was negative except for an occasional red blood cell.

Roentgenograms of the upright abdomen revealed no free air under the diaphragms and an increased density in the epigastrium. Retrograde pyelograms were normal in appearance.

Surgical intervention was deferred and conservative therapy instituted. The patient improved steadily and was discharged on the eleventh hospital day, asymptomatic except for residual tenderness in the epigastrium. He continued to improve until March 31, 1940 when, shortly after an airplane trip, he became nauseated and vomited. Thereafter he vomited from one to three times daily without nausea. On April 3, 1940, he was readmitted for study.

At this time his temperature, pulse, and respiration were normal. Blood pressure was 164/80. He appeared acutely ill and a large cystic mass filled the epigastrium. Exploratory laparotomy was performed on April 5, 1940, and the lesser peritoneal sac was found to be distended with approximately 1500 cubic centimeters of serosanguinous fluid. A pancreatic pseudocyst was drained with two soft rubber drains. Examination of the fluid revealed the presence of pancreatic ferments.

Drainage was profuse and continued for 25 days, when it ceased abruptly. The mass began to re-form and 6 days later operation was performed to re-establish drainage. This persisted for 2 months and caused considerable excoriation of the surrounding skin.

On July 12, 1940, a second laparotomy revealed a rent 3 centimeters in length in the anterior surface of the pancreas. This was closed with interrupted chromic catgut sutures and drains placed down to this area. Postoperatively, the volume of drainage steadily decreased, and on August 2, 1940, patient was discharged to be followed in the outpatient clinic. Six weeks after discharge the fistula closed, and the epigastric mass reappeared. The patient was readmitted and given conservative management. The mass disappeared in 10 days. The patient was discharged, and throughout the next 12 months was seen at frequent intervals in the outpatient department. The cyst recurred and was evacuated on 10 occasions by aspiration, yielding amounts varying from 750 to 1800 cubic centimeters. During this period, he occasionally exhibited evidence of hypoglycemia. He was admitted for study, and though the fasting blood sugar levels were at the lower limits of normal, the glucose tolerance curves were normal and his symptoms could not be reproduced by starvation.

The mass was still present 14 months after the last operation in July 1940. The patient was readmitted and on September 24, 1941, through a high left rectus incision, an antecolic cystojejunostomy was performed, two layers of interrupted silk sutures being used. Postoperative course was uneventful, and he was discharged from the hospital on October 12, 1941.

One year later, he was readmitted for study. The opening into the cyst could not be demonstrated on fluoroscopic examination of the barium-filled intestine. Glucose tolerance tests were normal.

Nothing further was heard from the patient until April 1, 1946, when he was transferred to a nearby army camp. He had entered the service early in 1943 and later was taken prisoner. He had been well throughout this period and had suffered no symptoms of hypoglycemia even while on a very low caloric diet during a 9 month period of incarceration in an enemy prison camp. At the time of examination, he appeared to be well nourished and in excellent health. No abdominal mass or tenderness could be detected. All laboratory studies, including glucose tolerance tests, were within normal limits.

DISCUSSION

The etiology and classification of pancreatic cysts are matters largely of academic interest, since treatment is in nearly all cases identical. Exploration is strongly indicated in every instance of a palpable upper abdominal mass for several reasons. An operable malignant lesion may be present in association with the cystic mass. Temporization in the case of a true or pseudocyst may allow spontaneous or traumatic rupture to occur. In a series of 6 cases of rupture reported by Koucky, there were 4 deaths (66 per cent mortality). Moreover, chances of spontaneous internal drainage or regression are rare.

Of the three methods available for treatment, internal drainage is the treatment of choice. Total excision is an ideal seldom attainable. External drainage or marsupialization offers the advantages of ease of performance and low mortality, but entails prolonged drainage, varying degrees of skin excoriation, and the possibility of cyst recurrence.

Properly performed internal drainage, while presenting a more difficult technical problem, secures adequate drainage without external irritation or need for prolonged dressings. The loss of fluid, enzymes, or electrolytes is obviated by their passage into the alimentary tract for utilization or absorption. The experience of other authors, together with the 2 cases reported, does not substantiate the tentative objection that internal drainage allows ingress of gastrointestinal juices to keep active inflammation in the cyst wall, and thus to encourage persistence of the cyst cavity. Roentgenologic studies at various time intervals following internal drainage usually fail to reveal filling of the cyst or any abnormality of the gastrointestinal tract at the site of the anastomosis.

Cystojejunostomy is preferable to cystogastrostomy (10) or cystocholecystostomy because of the accessibility of jejunal loops and avoidance of tension on the suture lines. Use of the gall bladder for anastomosis seems to be decidedly unphysiological and is contraindicated in the presence of coexistent biliary disease. A two layer anastomosis is used, and the stoma is made adequate (3 to 4 centimeters).

The question of pancreatitis is to be considered apart from that of cysts, even though it may be a predecessor. The treatment of the acute form is reasonably well established, is conservative, and surgical intervention is indicated only when diagnosis is not well established or upon appearance of a mass. Pancreatic abscess subsequent to acute pancreatitis requires drainage by catheter or marsupialization similar to cysts. Fistula formation can result and the drainage from this type of fistula causes marked skin irritation.

Manifestations of pancreatic insufficiency (hyperglycemia, abnormal glucose tolerance tests, digestive disturbances, and steatorrhea) are reported to accompany pancreatic cysts in relatively few instances. Tests for pancreatic function should be performed routinely and the presence of chronic pancreatitis ascertained. If present, medical management alone is indicated.

The results obtained with internal drainage reported by Adams and Warren, as well as in the 2 cases reported, would seem to compare favorably in morbidity and mortality with other methods of treatment. This is indicated by the satisfactory results which were obtained in each of the 2 reported cases after recurrences had followed previous attempts at external drainage.

SUMMARY

A brief review of the problem of pancreatic cysts is presented.

The frequent association of trauma is stressed as well as antecedent pancreatitis in certain cases.

Methods for treatment are outlined and the merits and disadvantages of each considered.

In the light of recent experience, internal drainage of pancreatic cysts which cannot be totally excised is the method of choice.

CICATRICIAL CONTRACTURES OF THE THUMB

FORREST YOUNG, M D , F A C S , Rochester, New York

CONTRACTURE limiting function of the thumb can occur in any of the surrounding soft tissue structures

However, most motion limiting contractures of the thumb are due to injuries to, or losses of, skin of the palm, thenar eminence, or thumb-index web. It is true that scar tissue may extend deeply but, in most instances, the problem is mainly one of supplying sufficient good skin to allow free motion after the limiting scar has been removed.

In the normal hand the skin is so constructed that it fits snugly when the hand is at rest but can glide or fold to allow motion from this position. When the thumb is in maximum abduction, the palmar skin and that over the thenar eminence are stretched smooth, while the skin between the thumb and index finger is drawn out into a web. On true adduction, the skin of the thenar eminence and adjacent palm folds in accordion fashion in lines parallel to the palmar creases, while the thumb-index web completely reverses from the widely abducted position and becomes relaxed into folds transverse to the line between thumb and index finger. On the motion of opposition-adduction the skin of the thumb-index web,

thenar eminence, and adjacent palm becomes one functioning unit, the skin folding in parallel lines radiating outward from a point at the base of the index finger and then curving circularly around the base of the thumb from the proximal phalangeal joint to the cleft between the thenar and hypothenar eminence (Fig 1).

It is obvious that the ideal replacement of skin over this moving area must be supple, large enough to accommodate to the extremes of motion, and set into the area in a manner which will not allow the formation of restraining scar lines.

PRINCIPLES OF CORRECTION

In most adduction contractures of the thumb, skin replacement is the key to complete correction. This skin must be set into the hand intelligently if full correction is to be maintained. The skin replaced should join normal skin in line with the natural folds present when the thumb is in adduction or opposition-adduction. No suture line should cross the roughly triangular space formed by the thenar eminence, proximal palmar flexion creases, and the thumb-index web. In addition, the new skin covering should not join the normal skin along the line of the web formed between the abducted thumb and the index finger. This

From the Division of Plastic Surgery, Division of Surgery, University of Rochester School of Medicine and Dentistry.

Fig 1 Schematic drawing made from photographs of normal hand to show the mobility of the skin and the

lines of folding which are present when the thumb is in various positions

is commonly made because most scar-
tures of the thumb are primarily due
ring on only one side of the hand, the
de being unaffected. This is so because
urns and similar injuries of the hands
eived in such a manner that one or the
either dorsal or volar aspect, receives
nt of the trauma. It should, however,
ne in mind that if the replaced skin is
to normal skin where the scar excision
a suture line will usually fall in the ab-
n fold between the thumb and index

Even though the correction be com-
this scar line will later contract and limit
tion

METHODS

ere are four possible methods which may
ed singly or in combination in the correc-
f thumb contractures due to scar replace-
of lost skin

Transposition of flaps. If there is a thin,
ascularized web between the thumb and
finger, a Z transposition of flaps may be
ient to deepen the thumb-index cleft sat-
only. If enough tissue is available, this
adequate procedure. The suture lines
within the correct areas and recontracture
e lines of junction are not likely to occur.
rious modifications of Z-plasty are useful
e correction of all scar bridges and it does
some usefulness in relieving thumb con-
tures. However, this usefulness is limited
cannot be used when there has been loss

Fig 2 a, Scar contracture limiting extension and ab-
duction of the thumb. This occurred following a midline
incision made in a primary repair of the flexor tendon. b,
Correction by tendon graft, covering tendon with soft
tissues, and free full thickness skin graft.

and scar replacement of palmar or thenar skin.
Even in the correction of thumb-index webs,
the amount of tissue available for transposi-
tion is often insufficient to allow complete alle-
viation of the contracture. I look upon the Z
transposition of flaps in most instances of scar
contracture as an adjunct in the correction.
They are either used to gain partial correction
prior to a planned, more complete operation,
or as partial covering of the defect created by
complete release, the remaining defect being
covered with free skin grafts.

2. Correction by local flaps. It is uncom-
mon that the shift of local flaps is applicable
in the correction of scar contractures of the
thumb. In deep but limited scars of the cen-
tral palm which limit abduction of the thumb

Fig 3 a, Extreme limitation of extension and abduction
to scar following gunpowder explosion. b, Diagram of
flap shift (1, 2) and free split thickness skin graft (3)
over area from which flap was taken. c, d, Result. Good
was shifted into the thumb-index web and over the
ar surface of the thumb. This allows good spread with

out restraining bands between the thumb and index finger
and, of course, gets the thumb into opposable position. The
line of junction of the graft and flap is, however, incorrect
and because of this abduction is limited about 30 per cent.
Perhaps the greatest advantage in this type of correction is
that it can be done in one step.

CICATRICIAL CONTRACTURES OF THE THUMB

FORREST YOUNG, M D , F A C S , Rochester, New York

CONTRACTURE limiting function of the thumb can occur in any of the surrounding soft tissue structures. However, most motion limiting contractures of the thumb are due to injuries to, or losses of, skin of the palm, thenar eminence, or thumb-index web. It is true that scar tissue may extend deeply but, in most instances, the problem is mainly one of supplying sufficient good skin to allow free motion after the limiting scar has been removed.

In the normal hand the skin is so constructed that it fits snugly when the hand is at rest but can glide or fold to allow motion from this position. When the thumb is in maximum abduction, the palmar skin and that over the thenar eminence are stretched smooth, while the skin between the thumb and index finger is drawn out into a web. On true adduction, the skin of the thenar eminence and adjacent palm folds in accordion fashion in lines parallel to the palmar creases, while the thumb-index web completely reverses from the widely abducted position and becomes relaxed into folds transverse to the line between thumb and index finger. On the motion of opposition-adduction the skin of the thumb-index web,

thenar eminence, and adjacent palm function as one functioning unit, the skin forming parallel lines radiating outward from the base of the index finger and thenar, particularly around the base of the thumb proximal phalangeal joint to the base of the thenar and hypothenar eminence.

It is obvious that the ideal replacement skin over this moving area must be large enough to accommodate the range of motion, and set into the area in such a way which will not allow the formation of permanent scar lines.

PRINCIPLES OF CORRECTION

In most adduction contractures of the thumb, skin replacement is the key to correction. This skin must be set intelligently if full correction is to be maintained. The skin replaced should be in line with the natural folds of the skin in line with the natural folds of the thumb is in adduction or opposition. No suture line should cross the triangular space formed by the thumb, index finger, and thenar eminence, proximal palmar flexor crease, or the thumb-index web. In addition, the skin covering should not join the thumb along the line of the web formed in the abducted thumb and the index

Fig. 1 Schematic drawing made from photographs of normal hand to show the mobility of the skin and the lines

of folding which are present when the thumb is in different positions

mistake is commonly made because most scar contractures of the thumb are primarily due to scarring on only one side of the hand, the other side being unaffected. This is so because most burns and similar injuries of the hands are received in such a manner that one or the other, either dorsal or volar aspect, receives the brunt of the trauma. It should, however, be borne in mind that if the replaced skin is joined to normal skin where the scar excision ends, a suture line will usually fall in the abduction fold between the thumb and index finger. Even though the correction be complete, this scar line will later contract and limit abduction.

METHODS

There are four possible methods which may be used singly or in combination in the correction of thumb contractures due to scar replacement of lost skin.

1 Transposition of flaps. If there is a thin, well vascularized web between the thumb and index finger, a Z transposition of flaps may be sufficient to deepen the thumb-index cleft satisfactorily. If enough tissue is available, this is an adequate procedure. The suture lines fall within the correct areas and recontracture of the lines of junction are not likely to occur.

Various modifications of Z-plasty are useful in the correction of all scar bridges and it does have some usefulness in relieving thumb contractures. However, this usefulness is limited. It cannot be used when there has been loss

Fig 2 a, Scar contracture limiting extension and abduction of the thumb. This occurred following a midline incision made in a primary repair of the flexor tendon. b, Correction by tendon graft, covering tendon with soft tissues, and free full thickness skin graft.

and scar replacement of palmar or thenar skin. Even in the correction of thumb-index webs the amount of tissue available for transposition is often insufficient to allow complete alleviation of the contracture. I look upon the Z transposition of flaps in most instances of scar contracture as an adjunct in the correction. They are either used to gain partial correction prior to a planned, more complete operation, or as partial covering of the defect created by complete release, the remaining defect being covered with free skin grafts.

2 Correction by local flaps. It is uncommon that the shift of local flaps is applicable in the correction of scar contractures of the thumb. In deep but limited scars of the central palm which limit abduction of the thumb

Fig 3 a, Extreme limitation of extension and abduction due to scar following gunpowder explosion. b, Diagram of local flap shift (1, 2) and free split thickness skin graft (3) to cover area from which flap was taken. c, d, Result. Good skin was shifted into the thumb index web and over the volar surface of the thumb. This allows good spread with

out restraining bands between the thumb and index finger and, of course, gets the thumb into opposable position. The line of junction of the graft and flap is, however, incorrect and because of this abduction is limited about 50 per cent. Perhaps the greatest advantage in this type of correction is that it can be done in one step.

Fig 4 a, Old burn contracture involving fingers and thumb b, The result from free split skin grafts and utilization of Z flaps 8 years after correction There has been no appreciable recontracture of the fingers and the palmar grafts stand up under manual labor The thumbs are in

functional position but the grafts were not well placed and hence there has been some circular contraction This illustrates that the graft edges should cross and not be in line with the lines of function In this instance a triangle should have gone across the midlateral line on either side

Fig 5 a, Adduction contracture of thumb from palmar scarring Scar caused by third degree burn b, Right and left hands for comparison 3 years after excision and release of scar, the defect being covered with a heavy split thickness skin graft The graft has not contracted appreciably, but the scar line at the junction of graft and skin in the thumb index web limits abduction Due to the contraction of this line about 40 per cent of the correction has been lost

a flap can be shifted from the ulnar side of the hand to cover the vital structures exposed by scar excision This flap is based proximally and usually includes all the skin and subcutaneous tissues of the hypothenar eminence and extends distally to the base of the ring and little fingers It is correct in principle and affords a one operation method of correcting limited deep palmar scars

In shifting flaps on the palm of the hand it is rarely advisable or possible to close the defect from which the flap was shifted The palmar skin is tight and inelastic and does not

mobilize easily The defect is covered with a free skin graft The maneuver is essentially a shift of the skin and subcutaneous tissue to cover structures over which a free skin graft cannot be safely applied and in so doing a defect which will take a free skin graft is substituted

In most instances in which release and excision of binding scar expose bone tendon or capsular structures of the thumb a flap can be shifted from the thenar eminence with its base distally over the metacarpal heads of the index and long fingers and a free skin graft can

b

be applied over the thenar eminence. This shift is not as well conceived as the hypothenar flap. Its blood supply is adequate, it provides good covering for the thumb and a satisfactory thumb-index web, but a scar line crosses the palm more or less transversely and does tend to limit wide abduction (Fig 3). These flaps are useful but should be limited in their application to small areas of deep scarring.

3. Correction by free skin grafts. In perhaps the majority of contractures about the thumb which limit motion, a fairly satisfactory correction results if the scar is cross-cut, dissected free and the skin supplemented with free skin grafts. The possibility of using this method hinges upon whether one thinks the limiting scar is superficial to the deep structures. In the usual burn contracture the scar is superficial enough that a plane of normal tissue is present between the external taut scar

and the nerves, vessels, and tendons. When this plane is found, the tight scar gapes and with minimal dissection its edges can be gradually pushed apart. The line in which the scar is severed should be selected with care, with the definite plan of having the edges of the defect so created to coincide with the lines of normal skin folding as nearly as possible. In some instances the scar is actually excised, but in more extensive scarring the defects are created by release of scar tension and insertion of grafts to increase the overall skin area (Fig 6). Again if possible one must avoid scar lines across the triangular palm area bounded by the thenar eminence and the palmar flexion creases, scar lines in the long axis of the thenar eminence and extended thumb, and between the thumb and the base of the index finger. If the edges of excision coincide with these lines, it is wiser to cross-cut normal skin and insert the graft in circular fashion to avoid the

Fig 8 a, Appearance of severe healed burn in an infant hand. There are three stubs of fingers which are almost completely grown together and contracted into hyperextension. The thumb is healed into the general mass. b, c, d, Scar dissected off dorsum of hand, fingers, and thumb, web resurfaced with heavy split skin grafts. In c, a triangular insert of skin into a cross-cut in the line of normal palmar skin between the base of the index finger and the thumb can be seen. Useful function gained.

Fig 9 a, Severely contracted palm following an avulsion injury. The thumb is held in pronounced adduction. b. In

such injuries it can be anticipated that the scar extends deeply. Its removal will expose the superficial vascular arch, digital nerves and flexor tendons. This will prevent the use of a free skin graft and in such instances flap repair is mandatory. The tube graft shown in b is first delayed and thinned as a flap. It is further thinned, and tubed at the time of attachment. The attachment to the dorsum of the hand just above the thumb index cleft allows smooth positioning and draping in the palm. The tube after attachment is severed, scar in hand released and excised flap unfolded, and placed in position at one operation.

possibility of limitation by linear contracture at these vulnerable points (Fig 7).

Of course, cicatricial contraction limiting thumb motion can occur on either dorsal or palmar aspect of the hand although the majority are mainly palmar. Free skin grafts are more gratifying on the dorsum of the hand. In fact, they are superior to any other method in correcting superficial scar contractures on the dorsum when the deep structures are uninvolved. The dorsal thumb index cleft can be satisfactorily reconstituted with free grafts if the points mentioned are kept in mind.

In my experience free skin grafts are not as satisfactory in correction of palmar scar contractures. In general the dorsal hand skin is usually in the stretched position when the hand is at rest or grasping. Under the same conditions the palmar skin is relaxed, wrinkled, and folded. This may be the reason that free skin grafts on the dorsal aspect of the hand remain beautifully smooth and eventually almost defy detection while on the palm they often tend to wrinkle and contract.

The character of the skin on the two surfaces is normally different. Free skin graft

Fig 10 a, Marked adduction of right thumb with minimal visible scar due to electrical burn. Such injuries go deeply. b, Full abduction obtained by correct insertion of flap after scar release and excision. c, The flap has been continued on into good skin to leave skin free of scar between the thumb and index finger.

more nearly resemble dorsal skin since there is normally almost no subcutaneous tissue present. The palmar skin is thicker, tougher, and pretty well padded. Free grafts do not have these characteristics and hence will not stand the hard usage that palmar skin must take at times. In spite of these objections fair to good corrections can be gained and permanently maintained by properly applied thick dermatome type free skin grafts in palmar contracture. The fact that good function of a badly contracted thumb can be gained in one operation in this manner weighs heavily in its favor. Moreover it can be used in children to gain functional position for growth, when flap transfers would be impossible (Fig 8). If partial recontracture occurs, the operation can be repeated after a year or two with still fewer operative steps than are necessary in correction by flaps.

4. Correction with pedicled flaps. There are a number of things to take into considera-

tion before making the decision to use pedicled flaps in the release of thumb contractures. In general this type of repair gives the best and most permanent correction. Perhaps the most important consideration is the depth of the scar and whether bone, nerve, or tendon repair must be carried out. If the scar is obviously deep, a flap must be used. The necessity for the later repair of deep structures makes a flap replacement necessary.

The location of the restraining scar must be considered. In general free skin grafts are more satisfactory on the dorsum of the hand, flaps on the palmar surface. The age of the patient is important. Infants are poor subjects for the immobilization necessary for a successful flap transfer. Flaps are also more risky in middle aged and elderly patients especially if they are obese. The ideal patient is a young thin male.

The fact that most indications for flap repair are on the palmar surface makes the prob-

lem more difficult since it is an awkward place to use a direct or delayed open flap

I have gradually evolved the following procedure. If flap repair is mandatory and the patient is in the middle aged, obese or moderately fat group, a flap of sufficient size is outlined on the contralateral lower anterior chest-abdominal wall with its base laterally and its long axis following the rib curve. Its end extends to the midline. About 50 per cent of this flap is elevated, thinned of fat, and delayed. When edema and induration have subsided, the remaining 50 per cent is elevated and thinned. At the third step the flap is completely elevated, tubed, and its medial end attached to the dorsum between the thumb and index finger (Fig 9). This attachment is left until the tube is soft and edema free. The attachment on the dorsal aspect just behind the thumb-index cleft allows the arm a normal position of right angled elbow flexion and forearm pronation while circulation is becoming established. At the fourth step the tube is severed at the chest, unfolded, and further thinned if necessary, the scar dissected free in the palm, and the flap fitted in place. At the final step after circulation is well established, the dorsally attached end is detached, trimmed,

and brought across the thumb-index line. I believe it is important to have the flap thinned to the point where no further intervention in the hand will be necessary thus preventing scarring as much as possible.

CONCLUSIONS

1 In the normal hand the skin of the thumb-index web, thenar eminence, and midpalm is a functioning unit which allows the thumb to move almost as a universal joint.

2 Scar contracture of this region can be relieved by one of four methods.

(a) Z plasty, applicable to thumb index webs only of rather minor restraining character, (b) local flap shifts, useful occasionally in small deep areas of scar, (c) free skin grafts, most suited to dorsal scars, but giving fair correction in superficial palmar contractures, particularly useful in infants, (d) thinned pedicle flap transfers, for deep palmar scarring and thenar eminence scarring.

3 Any one of the methods must be used intelligently so that no scar lines cross the folding areas of the thumb-index web, thenar eminence, and midpalm if a permanent maximum correction of the contracted thumb is to be obtained.

PEPTIC ULCER FOLLOWING SPLANCHNICECTOMY

A Report of Thirteen Cases

STEPHEN C MASON, M D, and H M POLLARD, M D, Ann Arbor, Michigan

THE purpose of the present report is to call attention to the effects of splanchnicectomy on the course of peptic ulcer. Since splanchnicectomy deprives the gastrointestinal tract of its sympathetic innervation, this resection can be expected to produce (a) alterations in visceral sensation and, possibly, (b) alterations in function of the stomach.

Afferent fibers from the gut pass from the sympathetic trunk to the dorsal root by way of the white rami communicantes and, like somatic afferents, their cell bodies are in the dorsal root ganglia. The pathway to the sympathetic trunk runs through the celiac plexus and then goes up through the diaphragm by way of the splanchnic nerves. The greater splanchnic nerve reaches the sympathetic trunk by branches to the fifth through the ninth or tenth thoracic ganglia, the lesser splanchnic usually to the ninth and tenth, and the lowest splanchnic to the last thoracic ganglia or the lesser splanchnic nerve (28). Preganglionic fibers pass outward from the cord by the same pathways. It has been demonstrated by Bain, Irving, and McSwiney (3) that afferent components of the splanchnic nerves enter the spinal cord by way of the white rami communicantes of all the spinal nerves from the third thoracic through the first lumbar. Balchum and Weaver have shown by distending the stomach of dogs with a balloon and watching for a certain typical change of respiration which indicated to them the threshold of pain, that the greater splanchnics carry most of the visceral afferents from the stomach and that the left carries more than the right. Their findings indicate also, that the distribution of afferent fibers from the stomach enter the cord in a widespread pattern. It was necessary to transect the posterior roots of the fourth

thoracic through the third lumbar ganglia before all pain from the stomach was abolished. They suggest further that though, under normal circumstances, the fibers mediating pain in the spinal segments of the eighth thoracic through the thirteenth thoracic ganglia carry the majority of impulses, it is possible that more impulses pass over other pathways when the main routes are interrupted and thus bring the pain threshold more toward the normal level.

The second group of effects of splanchnicectomy on the gastrointestinal tract concerns the alterations in function which might result from the interruption of the sympathetic efferent fibers of the stomach.

That there are alterations in function is suggested by a great many experimental studies. Most of the earliest investigation was centered about the production of peptic ulcers in animals by excision of the celiac ganglia, many of these workers reported lesions of the gastroduodenal mucosa varying from hyperemia to small ulcers. The reader may consult Koennecke for a review of this work.

More recently splanchnic nerve resections on dogs or rabbits were done by Durante, Brancati, Koennecke, and Koga, and they reported that ulcers developed in some of their animals. Alvarez and associates found gastric ulcers after 1 to 5 weeks in 5 of 7 rabbits surviving splanchnicectomy. Lium removed the celiac and mesenteric ganglia from 9 dogs and all of them developed a bloody diarrhea. At autopsy 4 of these dogs had peptic ulcers but Lium considered that inanition due to the diarrhea was partly responsible for the ulcers.

Keller (25) did thoracolumbar sympathectomies on 20 dogs and found no evidence of peptic ulcer when these animals were sacrificed after a postoperative period varying from 1 to 14 days. However, when thoraco-

lem more difficult since it is an awkward place to use a direct or delayed open flap

I have gradually evolved the following procedure. If flap repair is mandatory and the patient is in the middle aged, obese or moderately fat group, a flap of sufficient size is outlined on the contralateral lower anterior chest-abdominal wall with its base laterally and its long axis following the rib curve. Its end extends to the midline. About 50 per cent of this flap is elevated, thinned of fat and delayed. When edema and induration have subsided, the remaining 50 per cent is elevated and thinned. At the third step the flap is completely elevated, tubed, and its medial end attached to the dorsum between the thumb and index finger (Fig 9). This attachment is left until the tube is soft and edema free. The attachment on the dorsal aspect just behind the thumb-index cleft allows the arm a normal position of right angled elbow flexion and forearm pronation while circulation is becoming established. At the fourth step the tube is severed at the chest, unfolded, and further thinned if necessary, the scar dissected free in the palm, and the flap fitted in place. At the final step after circulation is well established, the dorsally attached end is detached, trimmed,

and brought across the thumb-index line. I believe it is important to have the flap thinned to the point where no further intervention in the hand will be necessary thus preventing scarring as much as possible.

CONCLUSIONS

1 In the normal hand the skin of the thumb-index web, thenar eminence, and midpalm is a functioning unit which allows the thumb to move almost as a universal joint.

2 Scar contracture of this region can be relieved by one of four methods.

(a) Z plasty, applicable to thumb index webs only of rather minor restraining character, (b) local flap shifts, useful occasionally in small deep areas of scar, (c) free skin grafts most suited to dorsal scars, but giving fair correction in superficial palmar contractures, particularly useful in infants, (d) thinned pedicle flap transfers, for deep palmar scarring and thenar eminence scarring.

carried out through Figures 1 to 6) Postsplanchnicectomy balloon kymograph 19 months after operation
12, carried out January 6, 1947

the influence of sodium luminal, the inhibitor response which had previously predominated was now converted to an augmentor response, and that current of any strength or frequency would produce only this response

Bilateral splanchnicectomy has been done on dogs by a number of investigators and the effects on the stomach observed. McCrea (30) did transabdominal splanchnotomies on dogs, cats, and rabbits, and observed the animals for 7 months following. The temporary changes he noted were increased depth of peristalsis and the stomach appeared small and tubular. These gradually became less marked and the organ returned to the normal state. However, permanent changes were noted (by x-ray examination) in the emptying time. The initial emptying time was markedly shortened and there was an appreciable decrease in the total emptying time. This fact he attributed to the increased activity of the stomach. McSwiney (32) tabulated the results of previous workers on

splanchnotomy and concluded that it produced accelerated function of the stomach. Cerqua studied the stomach after splanchnotomy and observed a decreased initial emptying time but, in his dogs, the total emptying time returned to normal after a few weeks. However, by following the emptying time by both x-ray examination and by means of gastric fistula, he found that, when olive oil or acid test meals were used, the total emptying time for these was greatly reduced from the expected values. He attributed this fact to a possibly decreased duodenal pyloric reflex. He found no constant change in the intensity or rate of gastric contraction when a balloon was inserted through the fistula so that he attributed the change in the initial emptying time to the presence of a patulous pylorus.

Barron (5, 7, 8) made a long series of balloon kymograph studies in 2 juvenile diabetic patients who had had a two stage splanchnicectomy. Shortly after left splanchnicectomy,

Fig 2 Control study II, Case

short periods of intense gastric motility were noticed, interrupted by short periods of quiescence. The periods of activity soon became longer and, occasionally, would last throughout a 4 to 5 hour period of observation or, more typically, there would be a period of motility which ended in gastric tetany. After a short period of quiescence the motility would resume and continue throughout the period of observation. After right splanchnicectomy, the results were similar. There was continued prolonged intense gastric motility and this lasted without change for the 7 months that one patient was followed. Gastric emptying time was studied in 1 of these patients and, while no significant decrease was noted after right unilateral splanchnicectomy, the average total emptying time decreased from 4 hours and 45 minutes to 3 hours and 30 minutes following the bilateral splanchnicectomy. Barron (6) concludes that splanchnicectomy removes the inhibitory effect of the sympathetic nervous system, inhibition being its predominant effect, and places

the stomach under the unopposed action of the vagus.

From these studies, the change in function, according to the reported work on man and on animals, seems to be in the direction of increased activity of the motor mechanism of the stomach. Whether this change in function is permanent has not been settled by the data in the literature. McCrea (30) acknowledges that the increase in activity seemed to be persistent, but he suggested that it probably would diminish in time. Much more evidence should be accumulated before these points will be established. Barron's 2 patients, it must be remembered, underwent splanchnicectomy for the treatment of diabetes, and though their insulin requirement was found to decrease postoperatively, they still required insulin. Barron states that the blood sugar level was well controlled by careful therapy with insulin and dextrose. But no data on this are given, and the fact that occasional "hypoglycemia periods" were observed and quickly corrected in his patients

12, carried out January 7, 1947

indicates the need of data which will avoid this possible source of error. Hypoglycemia and the fluctuations in blood sugar resulting from injections of insulin are potent factors connected with the production of gastric motility (14, 36). The 1 hypertensive patient studied after splanchnicectomy in the Gastroenterology Laboratory at the University of Michigan shows no evidence of a hypermotile stomach. Unfortunately, no presplanchnicectomy studies are available on this patient. The postplanchnicectomy balloon kymograph studies were begun 19 months after operation, shortly after a duodenal ulcer had been demonstrated by x-ray examination. Throughout the following 6 months tracings were made on 5 different occasions. Figure 1 through Figure 6 reproduce representative portions of these records. Throughout all the studies, the degree of quiescence is the most characteristic feature. The periods of activity which usually lasted 20 to 40 minutes consisted of large type I (tonus rhythm) and rather widely spaced type II (single spikes)

contractions. As a rule these periods occurred only once during a 3 to 4 hour study, and appeared while the patient was asleep, but somewhat more frequently when the patient was awake. A drop in the pH of the gastric juice to below 2.0 or 3.0 usually accompanied this activity. The insulin test, run after 3 control studies, shows the marked and early response of the gastric motility and secretory mechanism to hypoglycemia. The 15 minute samples of gastric juice were titrated and the output of hydrochloric acid during that period recorded—the wide column just above the time line represents the milligrams of hydrochloric acid output, the narrow column, the volume output of gastric juice. On the other records the single column represents the volume output. Despite the relatively small dose of insulin (10μ) given, a marked subjective response appeared during the hypoglycemic period, and 5 per cent glucose was started by intravenous drip, but not before the stomach had time to respond to the hypoglycemia.

Fig 3 Control study III, Case

If more studies of this nature, however, bear out the findings of Barron, what role will the increased motor activity play in the production of peptic ulcer, and what of the secretory mechanism under these conditions? Careful, detailed work on this subject might help establish the fact that such a thing as "vagal predominance" does occur when the opposing influence of the splanchnics is removed. And if under these circumstances, ulcer could be consistently produced in a significant percentage of dogs, the neurogenic theory of production of peptic ulcer would be on a sounder footing.

PRESENTATION OF 13 CASES

Bilateral supradiaphragmatic splanchnicectomy and lower dorsal ganglionectomy was done in these 13 cases as treatment for es-

sential hypertension. Preceding the operation, these patients were studied completely from the standpoint of their hypertension, but for the sake of brevity these findings are not included here. The hypertensive state was of such severity as to overshadow any other condition that was present and, because of this, splanchnicectomy was considered advisable in each case.

A postsplanchnicectomy diagnosis of peptic ulcer was made in 13 of 1,498 patients who registered at University Hospital from June, 1934, to June, 1945 and subsequently underwent a bilateral splanchnicectomy and lower dorsal ganglionectomy at this hospital. Preoperatively, 3 of these 13 patients had a proved diagnosis of peptic ulcer and 4 more had a presumptive diagnosis of ulcer made on the basis of reports of clinical and x-ray

Fig 4 Insulin test, Case 12

carried out January 8, 1947

findings preceding admission to the University Hospital. An additional 3 patients had symptoms which were only suggestive of ulcer, but, in 1 of these (Case 10) it is extremely likely that an active gastric ulcer was present at the time when the splanchnicectomy was performed.

Postoperatively, the diagnosis of peptic ulcer was proved in 9 cases while a presumptive diagnosis was reached in 3 other instances. In the remaining patient (Case 2), symptoms were suggestive of ulcer but it was not known whether or not the duodenal deformity which was seen 6 years postoperatively represented scarring which occurred before or after splanchnicectomy.

In brief, 8 of these 13 patients developed their first peptic ulcer preoperatively (Case 10 being included) while 4 developed their
